The second most frequently cited cause for unreliable clinical diagnosis identified by Ward et al. (1962) was the absence of specific explicit diagnostic criteria. Another innovation of DSM-III (American Psychiatric Association 1980, Spitzer et al. 1980) was the provision of specific and explicit diagnostic criterion sets that have facilitated the obtainment of more reliable clinical diagnosis. This innovation, however, has been problematic for the personality disorders, as it is difficult to provide a brief list of specific diagnostic criteria for the broad and complex behavior patterns that constitute a personality disorder. The only personality disorder to be diagnosed reliably in general clinical practice has been antisocial (Widiger and Samuel 2005b) and the validity of this diagnosis has been questioned precisely because of its emphasis on overt and behaviorally specific acts of criminality, irresponsibility, and delinquency (Hare 2003).

**Assessment**

There are assessment instruments, however, that will help psychiatrists obtain more reliable and valid personality disorder diagnoses. Semistructured interviews provide a researched set of required and recommended interview queries and observations to assess each of the personality disorder diagnostic criteria in a systematic, comprehensive, and replicable fashion. Semistructured interviews will obtain reliable diagnoses of personality disorders and are therefore the preferred method for their assessment in clinical research (McDermut and Zimmerman in press, Widiger in press). Psychiatrists can find the administration of semistructured interviews to be constraining (Westen 1997) but a major strength of semistructured interviews is their assurance through an explicit structure that each relevant diagnostic criterion has in fact been systematically assessed. Idiosyncratic and subjective interviewing techniques are much more likely to result in gender and culturally biased assessments (Garb 2005, Rogers 2003, Zimmerman 2003). The manuals that accompany a

---

When they determine that a personality disorder is present but the symptomatology fails to meet the criterion set for one of the ten specific personality disorders. A general definition of what is meant by a personality disorder is therefore helpful in determining whether the NOS diagnosis should in fact be provided. Points worth emphasizing with respect to the general criterion set provided in DSM-IV-TR Criteria: Personality Disorder are discussed in the following sections on the differential diagnosis, assessment, culture, epidemiology, and course of personality disorders.

**Differential Diagnosis**

One of the innovations of DSM-III was the provision of a multiaxial system for clinical diagnosis (American Psychiatric Association 1980, Spitzer et al. 1980). Prior to DSM-III psychiatrists rarely diagnosed a personality disorder when a patient’s symptoms met diagnostic criteria for an anxiety, mood, psychotic, or other mental disorder. In an extensive, widely cited, and historically influential study of psychiatric diagnosis, Ward et al. concluded that psychiatric diagnoses were excessively unreliable and that the greatest basis of disagreement was determining “whether the neurotic symptomatology or the characterological pathology is more extensive or ‘basic’” (Ward et al. 1962, p 202). They criticized the assumption that a clinician must choose between a “neurotic condition” and a personality disorder when both in fact appeared to be present. A personality disorder will predate the onset of most other mental disorders and its presence is likely to have a considerable impact on the course, treatment, and even etiology of the other mental disorder (Dolan-Sewell et al. 2001, Millon et al. 1996). DSM-III, therefore, moved the personality disorders to a separate axis so that psychiatrists could diagnose both conditions “rather than being forced to arbitrarily and unreliably make a choice between them” (Frances 1980, p 1050). The multiaxial system does appear to have been successful in encouraging psychiatrists to no longer make arbitrary distinctions between personality disorders and other mental disorders (Loranger 1990). Ironically, however, the placement of the personality disorders on a separate axis may also have contributed to the development of false assumptions and exaggerated expectations concerning the distinctions between personality disorders and other mental disorders with respect to etiology, pathology, and treatment (Krueger 2005).

The second most frequently cited cause for unreliable clinical diagnosis identified by Ward et al. (1962) was the absence of specific explicit diagnostic criteria. Another innovation of DSM-III (American Psychiatric Association 1980, Spitzer et al. 1980) was the provision of specific and explicit diagnostic criterion sets that have facilitated the obtainment of more reliable clinical diagnosis. This innovation, however, has been problematic for the personality disorders, as it is difficult to provide a brief list of specific diagnostic criteria for the broad and complex behavior patterns that constitute a personality disorder. The only personality disorder to be diagnosed reliably in general clinical practice has been antisocial (Widiger and Samuel 2005b) and the validity of this diagnosis has been questioned precisely because of its emphasis on overt and behaviorally specific acts of criminality, irresponsibility, and delinquency (Hare 2003).

**Assessment**

There are assessment instruments, however, that will help psychiatrists obtain more reliable and valid personality disorder diagnoses. Semistructured interviews provide a researched set of required and recommended interview queries and observations to assess each of the personality disorder diagnostic criteria in a systematic, comprehensive, and replicable fashion. Semistructured interviews will obtain reliable diagnoses of personality disorders and are therefore the preferred method for their assessment in clinical research (McDermut and Zimmerman in press, Widiger in press). Psychiatrists can find the administration of semistructured interviews to be constraining (Westen 1997) but a major strength of semistructured interviews is their assurance through an explicit structure that each relevant diagnostic criterion has in fact been systematically assessed. Idiosyncratic and subjective interviewing techniques are much more likely to result in gender and culturally biased assessments (Garb 2005, Rogers 2003, Zimmerman 2003). The manuals that accompany a

### DSM-IV-TR Criteria

**General Diagnostic Criteria for Personality Disorder**

A. An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture. This pattern is manifested in two (or more) of the following areas:

1. **cognition** (i.e., ways of perceiving and interpreting self, other people, and events)
2. **affectivity** (i.e., the range, intensity, lability, and appropriateness of emotional response)
3. **interpersonal functioning**
4. **impulse control**

B. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations.

C. The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood.

E. The enduring pattern is not better accounted for as a manifestation or consequence of another mental disorder.

F. The enduring pattern is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma).

semistructured interview also provide useful information for understanding the rationale of each diagnostic criterion, for interpreting vague or inconsistent symptomatology, and for resolving diagnostic ambiguities. There are currently five semistructured interviews for the assessment of the DSM-IV-TR (American Psychiatric Association 2000) personality disorders: (1) Diagnostic Interview for Personality Disorders (Zanarini et al. 1995), (2) International Personality Disorder Examination (Loranger 1999), (3) Personality Disorder Interview—IV (Widiger et al. 1995), (4) Structured Clinical Interview for DSM-IV-TR Axis II Personality Disorders (First and Gibbon 2004), and (5) Structured Interview for DSM-IV-TR Personality Disorders (Pfohl et al. 1997). Advantages and disadvantages of each particular interview have been discussed extensively (McDermut and Zimmerman 2005, in press, Widiger in press).

The Shedler-Westen Assessment Procedure—200 (SWAP-200) provides an additional alternative. The SWAP-200 is “a method for studying personality and personality pathology that strives to capture the richness and complexity of psychoanalytic constructs and formulations without forsaking the benefits of empirical rigor” (Shedler 2002, p 429). The SWAP-200 is a clinician rating form of 200 items, approximately half of which are equivalent to the existing DSM-IV-TR criterion sets. The rest were drawn from the psychoanalytic and personality disorder literature (Shedler 2002, Westen and Shedler 1999). SWAP-200 items are not ranked on the basis of an administration of a series of questions; instead, the SWAP-200 rating relies on “the empathically attuned and dynamically sophisticated clinician given free rein to practice his or her craft” (Shedler 2002, p 433). Quite a bit of research has been conducted using the SWAP-200 (Westen and Bradley 2005), although concerns have been raised regarding the validity of this research, particularly with respect to its use of a forced distribution of ratings (e.g., half of the items must be provided the lowest possible score and only a small minority can be provided the highest rating) that may artifactually compel the obtainment of improved convergent and discriminant validity (Clark 2007, Widiger and Samuel 2005b, Wood et al. in press).

The administration of an entire personality disorder semistructured interview can take 2 hours, an amount of time that is impractical in routine clinical practice. However, this time can be reduced substantially by first administering a self-report questionnaire that screens for the presence of the DSM-IV-TR personality disorders (Widiger et al. 2006). A psychiatrist can then confine the interview to the few personality disorders that the self-report inventory suggested would be present. Self-report inventories are useful in ensuring that all of the personality disorders are systematically considered and in alerting the clinician to the presence of maladaptive personality traits that might otherwise have been missed. There are a number of alternative self-report inventories that can be used, including (1) Minnesota Multiphasic Personality Inventory—2 personality disorder scales of Colligan et al. (1994), (2) Millon Clinical Multiaxial Inventory—III (Millon et al. 1997), (3) OMNI Personality Inventory (Loranger 2001), (4) Personality Diagnostic Questionnaire—4 (Bagby and Farvolden 2004), (5) Personality Assessment Inventory (Morey and Boggs 2004), (6) Schedule for Nonadaptive and Adaptive Personality Functioning (Clark et al. in press), (7) Wisconsin Personality Disorders Inventory (Klein et al. 1993), and (8) Coolidge Axis II Inventory (Coolidge and Merwin 1992). Advantages and disadvantages of each of them have also been discussed extensively (McDermut and Zimmerman 2005, in press, Millon et al. 1996, Widiger in press, Widiger et al. 2006).

Culture

Cultural biases are one potential source of inaccurate personality disorder diagnosis that are worth noting in particular (Garb 2005, Lopez and Guarnaccia 2005, Morey et al. 2005). One of the general diagnostic criteria for personality disorder is that the personality trait must deviate markedly from the expectations of a person’s culture (see DSM-IV-TR Criteria: Personality Disorder). The purpose of this cultural deviation requirement is to compel clinicians to consider the cultural background of the patient. A behavior pattern that appears to be aberrant from the perspective of one’s own culture (e.g., submissiveness or emotionality) could be quite normative and adaptive within another culture. The cultural expectations or norms of the psychiatrist might not be relevant or applicable to a patient from a different cultural background. However, one should not infer from this requirement that a personality disorder is primarily or simply a deviation from a cultural norm. Deviation from the expectations of one’s culture is not necessarily maladaptive, nor is conformity to one’s culture necessarily healthy. Many of the personality disorders may even represent (in part) extreme or excessive variants of behavior patterns that are valued or encouraged within a particular culture. For example, it is usually adaptive to be confident but not to be arrogant, to be agreeable but not to be submissive, or to be conscientious but not to be perfectionist.

Epidemiology

Virtually all patients will have had a characteristic manner of thinking, feeling, behaving, and relating to others prior to the onset of an Axis I disorder that could have an important impact on the course and treatment of the respective mental disorder (Dolan-Sewell et al. 2001, Mattia and Zimmerman 2001). Estimates of the prevalence of personality disorder within clinical settings are typically above 50% (Mattia and Zimmerman 2001). As many as 60% of inpatients within some clinical settings would be diagnosed with borderline personality disorder (BPD) (American Psychiatric Association 2000, Gunderson 2001) and as many as 50% of inmates within a correctional setting could be diagnosed with antisocial personality disorder (ASPD) (Derefinko and Widiger in press). Although the comorbid presence of a personality disorder is likely to have an important impact on the course and treatment of an Axis I disorder (Dolan-Sewell et al. 2001), the prevalence of personality disorder is generally underestimated in clinical practice, due in part to the failure to provide systematic or comprehensive assessments of personality disorder symptomatology and perhaps as well to the lack of funding for the treatment of personality disorders (Zimmerman and Mattia 1999).

Approximately 10–15% of the general population would be diagnosed with one of the ten DSM-IV-TR personality disorders, excluding personality disorder not otherwise specified (PDNOS) (Mattia and Zimmerman 2001, Torgersen et al. 2001). Table 82–1 provides prevalence
data reported by the best available studies to date for estimating the prevalence of individual personality disorders within a community population. All of these studies have important limitations, though, that qualify their results. For example, many of the studies sampled persons who would probably have less personality disorder pathology than a randomly selected sample (e.g., some studies have sampled persons without any history of Axis I psychopathology) and studies have used either the DSM-III (American Psychiatric Association 1980) or DSM-III-R (American Psychiatric Association 1987) criterion sets rather than DSM-IV-TR (American Psychiatric Association 2000). Nevertheless, the prevalence estimates are generally close to those provided in DSM-IV-TR. Prevalence rates for individual personality disorders will be discussed later in this chapter.

Comorbidity

There is also considerable personality disorder diagnostic co-occurrence (Bornstein 1998, Clark 2007, Livesley 2003). Patients who meet the DSM-IV-TR diagnostic criteria for one personality disorder are likely to meet the diagnostic criteria for another. Table 82–2 provides the co-occurrence among the DSM-III-R (American Psychiatric Association 1987) personality disorder diagnoses that were obtained for the development of DSM-IV-TR (American Psychiatric Association 1994). DSM-IV-TR instructs psychiatrists that all diagnoses should be recorded because it can be important to consider, for example, the presence of antisocial traits in someone with a BPD or the presence of paranoid traits in someone with a dependent personality disorder (DPD). However, the extent of diagnostic co-occurrence is at times so extensive that most researchers prefer a more dimensional description of personality (Cloninger 2000, Livesley 2003, Oldham and Skodol 2000, Widiger and Samuel 2005a). Diagnostic categories provide clear, vivid descriptions of discrete personality types but the personality structure of actual patients might be more accurately described by a constellation of maladaptive personality traits. Several studies

Sites used DSM-III-R criterion sets. Data obtained for purposes of informing the development of the DSM-IV-TR personality disorder diagnostic criteria.

have demonstrated that much of the personality disorder diagnostic co-occurrence is readily explained if they are understood as maladaptive variants of general personality structure (Lynam and Widiger 2001, O’Connor 2005).

In 1999, a DSM Research Planning Conference was held under joint sponsorship of the American Psychiatric Association and the National Institute of Mental Health, the purpose of which was to set research priorities that would optimally inform the authors of future editions of the diagnostic manual. A work group that concerned personality disorders focused its attention on the conceptual and empirical support for a dimensional model of classification (First et al. 2002). The Nomenclature Work Group also recommended that efforts toward a dimensional model of classification be developed for the personality disorders. “If a dimensional system of personality performs well and is acceptable to clinicians, it might then be appropriate to explore dimensional approaches in other domains” (Rounsaville et al. 2002, p 13). This conference was followed by a series of international conferences, each covering a particular domain of the diagnostic manual. The first of this series was devoted to setting a research agenda that would be most effective in leading the field toward a dimensional classification of personality disorder (Widiger et al. 2005).

A number of alternative dimensional models of personality disorder have been developed. Perhaps not surprisingly, as they are all attempting to do largely the same thing, it is evident that these alternative models can be well integrated within a common hierarchical structure defined at one level by four (or five) broad domains of general personality structure: extraversion versus introversion, antagonism versus agreeableness, constraint versus impulsivity, and emotional dysregulation versus emotional stability (Widiger and Simonsen 2005). These four broad domains correspond closely to four of the five domains of the five-factor model of general personality structure.

Five broad domains of personality functioning have been identified empirically through the study of the languages of a number of different cultures (Ashton and Lee 2001). Language can be understood as a sedimentary deposit of the observations of persons over the thousands of years of the language’s development and transformation. The most important domains of personality functioning would be those with the greatest number of words to describe and differentiate their various manifestations and nuances, and the structure of personality will be evident by the empirical relationship among the trait terms. Such lexical analyses of languages have typically identified five fundamental dimensions of personality: extraversion (or positive emotionality), antagonism, conscientiousness, neuroticism (or negative affectivity), and openness (or unconventionality). Each of these five broad domains can be differentiated further in terms of underlying facets. For example, the facets of antagonism versus agreeableness include suspiciousness versus trusting gullibility, tough-mindedness versus tender-mindedness, confidence and arrogance versus modesty and meekness, exploitation versus altruism and sacrifice, oppositionalism and aggression versus compliance, and deception and manipulation versus straightforwardness and honesty (McCrae and Costa 1999). Perhaps most importantly for the purposes of this chapter, each of the DSM-IV-TR personality disorders can be understood as maladaptive variants of these personality traits that are evident in all persons to varying degrees (Clark 2007, Lynam and Widiger 2001, Mullins-Sweatt and Widiger 2006, Saulsman and Page 2004, Widiger et al. 2002).

Table 82–3 provides a description of the DSM-IV-TR personality disorders in terms of this five-factor model. For example, ASPD is primarily defined in terms of antagonism (i.e., aggressive, exploitative, callous, ruthless, and mistrustful) and low conscientiousness (irresponsible, neglectful, and rash), but the five-factor model description goes beyond the DSM-IV-TR to include additional traits emphasized within the broader literature on psychopathy, including arrogance, glib charm (low self-consciousness), and fearlessness (low vulnerability), and lack of empathy (callousness) (Lynam and Widiger 2007). The five-factor description even includes the trait of low anxiousness that was emphasized by Cleckley (1941) but not included in either DSM-IV-TR (American Psychiatric Association 2000) or even most studies of psychopathy (Hare 2003).

Advantages of understanding personality disorders in terms of this dimensional model are the provision of more specific descriptions of individual patients (including adaptive as well as maladaptive personality functioning), the avoidance of arbitrary categorical distinctions, and the ability to apply the extensive amount of research on the heritability, temperament, development, course, and cross-cultural validity of general personality functioning to an understanding of personality disorders (Widiger and Trull 2007).

Course

Personality disorders must be evident since adolescence or young adulthood and have been relatively chronic and stable throughout adult life (see DSM-IV-TR Criteria: Personality Disorder). The World Health Organization (1992) International Classification of Diseases recognizes the existence of personality change secondary to catastrophic experiences and to brain injury or disease, but only the latter is included within DSM-IV-TR (American Psychiatric Association 2000). A 75-year-old man can be diagnosed with a DSM-IV-TR DPD but the symptoms must have been present throughout the entire duration of his adulthood (e.g., since the age of 18) unless the dependent behavior was a direct, explicit expression of a neurochemical disease or lesion.

The requirement that a personality disorder be evident since late adolescence and be relatively chronic thereafter has been a traditional means with which to distinguish a personality disorder from an Axis I disorder (Millon et al. 1996, Spitzer et al. 1980). Mood, anxiety, psychotic, sexual, and other mental disorders have traditionally been conceptualized as conditions that arise at some point during a person’s life and that are relatively limited or circumscribed in their expression and duration. Personality disorders, in contrast, are conditions that are evident as early as late adolescence (and in some instances prior to that time), are evident in everyday functioning, and are stable throughout adulthood. However, the consistency of this distinction across disorders has been decreasing with each edition of the DSM, as early onset and chronic variants of Axis I disorders are being added to the diagnostic manual (e.g., early onset dysthymia and generalized social phobia). Some researchers have in fact suggested abandoning the concept of personality disorder and replacing it with early onset and chronic variants.
of existing Axis I disorders (First et al. 2002). For example, avoidant personality disorder (AVPD) could become generalized social phobia and BPD could become an early onset and chronic mood dyscontrol. A precedent for this revision is that ICD-10 currently does not include a diagnosis of schizotypal personality disorder (STPD), including instead a diagnosis of schizotypal disorder that is an early onset and chronic variant of schizophrenia (World Health Organization 1992).

Etiology and Pathophysiology
A primary purpose of a diagnosis is to lead to scientific knowledge concerning the etiology for a patient’s condition and the identification of a specific pathology for which a particular treatment (e.g., medication) would ameliorate the condition (First and Tasman 2006). However, many of the mental disorders in DSM-IV-TR, including the personality disorders, may not in fact have single etiologies or even specific pathologies (Rutter 2003). The DSM-IV-TR personality disorders might be, for the most part, constellations of maladaptive personality traits that are the result of multiple genetic dispositions interacting with a variety of detrimental environmental experiences (Paris 2005, Widiger and Trull 2007).

Treatment
One of the mistaken assumptions or expectations of Axis II is that personality disorders are untreatable. General personality structure is not itself set in stone. Temporal stability coefficients for personality are only about 0.31 in childhood (contributing to the reluctance to diagnose personality disorders in childhood), 0.54 during years of college, 0.64 at age 30 and leveling off at 0.74 between ages of 50 and 70 (Roberts and DelVecchio 2000). These temporal stability coefficients document the consistency of personality over time, but they also indicate that some change can occur. Temporal stability of maladaptive personality traits might be even lower (Skodol et al. 2005), as such traits are often the focus of clinical treatment (Beck et al. 1990, Gunderson and Gabbard 2000, Millon et al. 1996, Paris 1998, Stone 1993, Young et al. 2003). Personality disorders are among the more difficult of mental disorders to treat, as they...
involves entrenched behavior patterns, some of which will be integral to a person's self-image (Millon et al. 1996, Stone 1993). Nevertheless, there is compelling empirical support to indicate that meaningful responsiveness to psychosocial and pharmacologic treatment does occur (Markovitz 2001, Perry et al. 1999, Sanislow and McGlashan 1998). Treatment of a personality disorder is unlikely to result in the development of a fully healthy or ideal personality structure, but clinically and socially meaningful change to personality structure and functioning does occur. In fact, given the considerable social, occupational, medical, and other costs that are engendered by such personality disorders as the antisocial and borderline, even marginal reductions in symptomatology can represent quite significant and meaningful public health care, social, and clinical benefits (Linehan 2001).

**The DSM-IV-TR Personality Disorders**

DSM-IV-TR includes 10 individual personality disorder diagnoses that are organized into three clusters: (a) paranoid, schizoid, and schizotypal (placed within an odd–eccentric cluster); (b) antisocial, borderline, histrionic, and narcissistic (dramatic–emotional–erratic cluster); and (c) avoidant, dependent, and obsessive–compulsive (anxious–fearful cluster) (American Psychiatric Association 2000). Each of these personality disorders, along with the two that are included in the appendix to DSM-IV-TR for disorders needing further study (i.e., passive–aggressive and depressive), will be discussed in turn.

**Paranoid Personality Disorder**

Paranoid personality disorder (PPD) is a personality disorder that has been in every edition of the American Psychiatric Association diagnostic manual. However, it has received limited empirical research (Blashfield and Intoccia 2000) due in part perhaps to attention of researchers shifting their interest from PPD to the STPD added to the 1980, third edition of the diagnostic manual (Parnas et al. 2005).

**Definition**

PPD involves a pervasive and continuous distrust and suspiciousness of the motives of others (American Psychiatric Association 2000) but the disorder is more than just suspiciousness. Persons with this disorder are also hypersensitive to criticism, they respond with anger to threats to their autonomy, they incessantly seek out confirmations of their suspicions, and they tend to be quite rigid in their beliefs and perceptions of others (Millon et al. 1996, Widiger et al. 1995). The presence of PPD is indicated by four or more of the seven diagnostic criteria presented in DSM-IV-TR Criteria 301.0.

**Differential Diagnosis**

PPD paranoid ideation is inconsistent with reality and is resistant to contrary evidence, but the ideation is not psychotic, absurd, inconceivable, or bizarre. PPD will also lack other features of psychotic and delusional disorders (e.g., hallucinations) and will be evident since early adulthood, whereas a psychotic disorder will become evident later within a person’s life or will remit after a much briefer period of time. Persons with PPD can develop psychotic disorders but to diagnose PPD in such cases the paranoid personality traits must be evident prior to and persist after the psychotic episode. If PPD preceded the onset of schizophrenia, then it should be noted that it was pre-morbid to the schizophrenia (American Psychiatric Association 2000). However, it may not be meaningful to diagnose a person with both PPD and schizophrenia, as the premorbid paranoid traits may, in some cases, have simply represented a prodromal phase of the schizophrenic pathology.

**Epidemiology and Comorbidity**

Trust versus mistrust is a fundamental personality trait along which all persons vary (McCrae and Costa 1999). Thirteen percent of the adult male population and six percent of the adult female population may be characteristically mistrustful of others (Costa and McCrae 1992). However, only 0.5–2.5% of the population are likely to meet the DSM-IV-TR diagnostic criteria for PPD (see Table 82–1). It is suggested in DSM-IV-TR that approximately 10–30% of persons within inpatient settings and 2–10% within
outpatient settings will have this disorder (American Psychiatric Association 2000), but the lower end of these rates may represent the more accurate estimate. It does appear that more males than females have the disorder (American Psychiatric Association 2000).

Paranoid personality traits will be evident in other personality disorders. Persons with AVPD will be socially withdrawn and apprehensive of others; borderline, antisocial, and narcissistic persons may be impatient, irritable, and antagonistic; and schizotypal persons may display paranoid ideation. The diagnosis of PPD will often co-occur with these other personality disorder diagnoses (see Table 82–2). Persons with PPD are prone to develop a variety of Axis I disorders, including substance-related, obsessive–compulsive anxiety, agoraphobic, and depressive disorders (American Psychiatric Association 2000).

Course
There is very limited research on the childhood antecedents and course of PPD. What is known is based largely on clinical experience. It is suggested that premorbid traits of PPD include social isolation, hypersensitivity, hypervigilance, social anxiety, peculiar thoughts, angry hostility, and idiosyncratic fantasies (American Psychiatric Association 2000). As children, they may appear odd and peculiar to their peers and they may not have achieved to their capacity in school. Their adjustment as adults would be particularly poor with respect to interpersonal relationships. They may become socially isolated or fanatic members of groups that encourage or at least accept their paranoid ideation. They might maintain a steady employment but will be difficult coworkers, as they will tend to be rigid, controlling, critical, blaming, and prejudicial. They are likely to become involved in lengthy, acrimonious, and litigious disputes that are difficult, if not impossible, to resolve (Millon et al. 1996, Stone 1993).

Etiology and Pathophysiology
There is only limited research on the heritability of PPD (Torgersen et al. 2000), but quite a number of studies have indicated a genetic contribution to the development of suspiciousness and mistrust (Bouchard and Loehlin 2001, Jang et al. 1998, Nigg and Goldsmith 1994). There is some support for a genetic relationship of PPD with schizophrenia but these findings have not always been replicated and the findings may have been due to the overlap of PPD with the STPD (Siever 1992). There is only limited support for a genetic relationship with delusional disorder, persecutory type (Nigg and Goldsmith 1994).

There are no systematic studies on possible psychosocial contributions to the development of PPD. There is some support for the contribution of excessive parental criticism and rejection but there has not yet been adequate prospective longitudinal studies (Miller et al. 2001). Paranoid belief systems could develop through parental modeling, a history of discriminatory exploitation or abandonment, and the isolation of anger, resentment, and bitterness onto a group that is external to and distinct from oneself. Mistrust and suspicion is often evident in members of minority groups, immigrants, refugees, and other groups for whom such distrust can be a realistic and appropriate response to the social environment. It is conceivable that a comparably sustained experience from childhood and adolescence could contribute to the development of excessive paranoid beliefs that are eventually applied inflexibly and inappropriately to a wide variety of persons, but it can be very difficult to determine what is excessive or unrealistic suspicion and mistrust within a member of an oppressed minority (Alarcon 2005). Paranoid suspiciousness could in fact be more closely associated with prejudicial attitudes, wherein a particular minority group in society becomes the inappropriate target of one’s anger, blame, and resentment.

There has been little consideration given to the neurophysiological concomitants of nonpsychotic paranoid personality traits. More attention has been given to cognitive, interpersonal, and object-relational models of pathology. Paranoid beliefs do appear to have a self-perpetuating tendency resulting from the narrow and limited focus on signs and evidence for malicious intentions (Young and Klosko 2005). The pathology of PPD, from this perspective, is inherent to the irrationality of the person’s belief systems and is sustained by the biased information processing. There may also be an underlying motivation or need to perceive threats in others and to externalize blame that help to sustain the accusations and distortions (Gabbard 2000a, Millon et al. 1996).

Treatment
There are no systematic studies on the treatment of PPD. Persons with PPD would rarely seek treatment for their feelings of suspiciousness and distrust. They will experience these traits as simply accurate perceptions of a malevolent and dangerous world (i.e., ego syntonic). They may not consider the paranoid attributions to be at all problematic, disruptive, or maladaptive. They will not be delusional, but they will also fail to be reflective, insightful, or self-critical. They may recognize only that they have difficulty controlling their anger and getting along with others. They might be in treatment for an anxiety, mood, or substance-related disorder or for various marital, familial, occupational, or social (or legal) conflicts that are secondary to their personality disorder, but they will also externalize the responsibility for their problems and will have substantial difficulty recognizing their own contribution to their internal dysphoria and external conflicts. They will consider their problems to be due to what others are doing to them, not to how they perceive, react, or relate to others.

The presence of paranoid personality traits will complicate the treatment of an Axis I disorder or a relationship problem (Dolan-Sewell et al. 2001). Trust is central to the development of an adequate therapeutic alliance, and yet it is precisely the absence of trust that is central to this disorder (Bender 2005). It can be tempting to be less forthright and open in the treatment of excessively suspicious persons because they will distort, exaggerate, or escalate minor errors, misunderstandings, or inconsistent statements. However, therapists will find that they weave an increasingly tangled web as they walk gingerly around the truth. And, persons with PPD will seize upon any kernel of deception to confirm their suspicion that the therapist is not to be trusted. It is preferable to be especially forthright and precise with paranoid patients. Details that will be inconsequential and of no interest to most patients can be important to provide to persons with PPD so that they are ensured that nothing is being withheld or hidden from them.
Clinicians agree on several general principles in the treatment of paranoid personality traits (Beck et al. 1990, Gabbard 2000a, Millon et al. 1996, Stone 1993). It is usually pointless and often harmful to rapport to confront (or argue with) the paranoid beliefs. Such efforts may only alienate the patient and confirm his or her suspicions. The therapist should maintain a sincere and consistent respect for their autonomy and for their right to make their own decisions. However, one should not attempt to ingratiate oneself by being overly acquiescent and compliant. This can appear to be obviously patronizing, insincere, or manipulative. The goal is to develop, in a nonthreatening way, more self-reflection and self-awareness (e.g., recognition of the contribution of the paranoid traits and behaviors to the difficulties they are experiencing within their lives). A useful approach can be to communicate a sincere and respectful willingness to explore the implications, logic, and reality of the suspicions (Beck et al. 1990). Whenever one appears to be endangering rapport by moving too quickly, one should retreat to a more neutral and accepting position.

One must also be careful to avoid defensive reactions to the inevitable accusations. Any one of the conflicts they have had with others can develop within the therapeutic relationship (Gabbard 2000a) and their tendency to be contentious, rigid, accusatory, suspicious, and litigious can tax the empathy and patience of the therapist. One must attempt to maintain an empathic concern for their feelings of betrayal and reassure them in an understanding, forthright manner that is neither patronizing nor disrespectful. Termination of treatment may at times be necessary if continuation would only result in further acrimony.

The suspicions, accusations, and acrimony will often make the person with PPD a poor candidate for group therapies (Piper and Ogrodniczuk 2005). There is the potential to learn much about themselves within a group, but it is usually very difficult for them to develop the feelings of trust, respect, and security that are necessary for successful group therapy. Their propensity to make unfair hostile accusations will alienate them from other group members, and they may quickly become a scapegoat for difficulties and conflicts that develop within the group.

There have been a variety of studies on the pharmacologic treatment of psychotic paranoid ideation and schizotypal personality disorder (which often includes paranoid personality traits) but little to no research on the pharmacologic responsivity of the nonpsychotic suspiciousness and ego-syntonic paranoid ideation of PPD (Markovitz 2001, Perry et al. 1999, Soloff 2005). Persons with PPD may also perceive the use of a medication to represent an effort to simply suppress or control their accusations and suspicions rather than to respectfully consider and address them. However, they may be receptive and responsive to the benefits of a medication to help control feelings of anxiousness or depression that are secondary to their personality disorder.

**Schizoid Personality Disorder**

Schizoid personality disorder (SZPD) has been in every edition of the American Psychiatric Association diagnostic manual. However, it has received limited empirical research (Blashfield and Intoccia 2000) due in part perhaps to attention of researchers shifting their interest from SZPD to the STPD added to the 1980, third edition of the diagnostic manual (Kalus et al. 1993, Parnas et al. 2005).

**Definition**

SZPD is a pervasive pattern of social detachment and restricted emotional expression. Introversive (versus extraversion) is one of the fundamental dimensions of general personality functioning (McCrae and Costa 1999). Facets of introversion include low warmth (e.g., cold, detached, and impersonal), low gregariousness (socially isolated, withdrawn), and low positive emotions (reserved, constricted or flat affect, and anhedonic), which define well the central symptoms of SZPD (Widiger et al. 2002, see Table 82–3). The presence of SZPD is indicated by four or more of the seven diagnostic criteria presented in DSM-IV-TR Criteria 301.20.

**Differential Diagnosis**

SZPD can be confused with the STPD and AVPD, as both involve social isolation and withdrawal (Kalus et al. 1993, Widiger et al. 1995). STPD, however, also includes an intense social anxiety and cognitive-perceptual aberrations.

---

**DSM-IV-TR Criteria 301.20**

**Schizoid Personality Disorder**

A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Neither desires nor enjoys close relationships, including being part of a family
2. Almost always chooses solitary activities
3. Has little, if any, interest in having sexual experiences with another person
4. Takes pleasure in few, if any, activities
5. Lacks close friends or confidants other than first-degree relatives
6. Appears indifferent to the praise or criticism of others
7. Emotional coldness, detachment, or flattened affectivity

B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder; and is not due to the direct physiological effects of a general medical condition.

Note: if criteria are met prior to the onset of schizophrenia, add “premorbid,” e.g., schizoid personality disorder (premorbid).

The major distinction with AVPD is the absence of an intense desire for intimate social relationships. Both avoidant and schizoid persons are introverted, but the schizoid person is driven by an anhedonic disinterest in relationships (extremely low in positive emotionality) whereas the avoidant person is driven by a self-conscious neuroticism. Avoidant persons will exhibit substantial insecurity and inhibition (high neuroticism), whereas the schizoid person is largely indifferent toward the reactions or opinions of others (Widiger et al. 1995, 2002).

The presence of premorbid schizoid traits is considered to have prognostic significance for the course and treatment of schizophrenia (Siever 1992) but, more importantly, it might not be meaningful to suggest that a person has a schizoid personality disorder that is independent of or unrelated to a comorbid schizophrenia. The negative, prodromal, and residual symptoms of schizophrenia resemble closely the features of SZPD. Once a person develops schizophrenia, a diagnosis of SZPD can become rather pointless, as all of the schizoid symptoms can then be understood as (prodromal or residual) symptoms of schizophrenia.

Epidemiology and Comorbidity
Approximately half of the general population will exhibit introversion within the normal range of functioning. However, only a small minority of the population would be diagnosed with a schizoid personality disorder (Mattia and Zimmerman 2007). Estimates of the prevalence of SZPD within the general population have been less than 1% (see Table 82–1) and SZPD is among the least frequently diagnosed personality disorders within clinical settings. Many of the persons who were diagnosed with SZPD prior to DSM-III are probably now diagnosed with either the avoidant or the STPD (Widiger et al. 1988) and prototypic (pure) cases of SZPD are likely to be quite rare within the population.

Course
There are few systematic studies on the childhood antecedents of avoidant and adult course of SZPD. Persons with SZPD are likely to have been socially isolated and withdrawn as children. They may not have been accepted well by their peers and may have been the brunt of some ostracism (American Psychiatric Association 2000). As adults, they will have few friendships (Stone 1993). The friendships that do occur are likely to have been initiated by their peers or colleagues. They will have had few sexual relationships and may never marry. Relationships will fail to the extent to which the other person desires or needs emotional support, warmth, and intimacy. Persons with SZPD may do well and even excel within an occupation, as long as substantial social interaction is not required. They would prefer to work in isolation. They may eventually find employment and a relationship that is relatively comfortable, but they could also drift from one job to another and remain isolated throughout much of their life. If they do eventually become a parent, they will have considerable difficulty providing warmth and emotional support, and they may appear neglectful, detached, and disinterested.

Etiology and Pathophysiology
A fundamental distinction for schizophrenic symptomatology is between positive and negative symptoms (Walker et al. 2004). Positive symptoms include hallucinations, delusions, inappropriate affect, and loosened associations; negative symptoms include flattened affect, aloxia, anhedonia, and avolition. SZPD could be conceptualized as representing subthreshold negative symptoms, comparable to the subthreshold positive symptoms (cognitive–perceptual aberrations) that predominate STPD (Miller et al. 2001, Parnas et al. 2005). However, a genetic link of SZPD to schizophrenia that cannot be accounted for by comorbid STPD symptomatology has not been well established (Miller et al. 2001). There is only limited research on the heritability of SZPD (Torgersen et al. 2000) but quite a number of studies have indicated a genetic contribution for the personality dimension of introversion (Bouchard and Loehlin 2001, Jang et al. 1998, Jang and Vernon 2001). The pathology of SZPD is considered to be an anhedonic deficits, or an excessively low ability to experience positive affect, which is also central to the general personality trait of introversion (Rothbart et al. 2000). Psychosocial models for the etiology of SZPD are lacking. It is possible that a sustained history of isolation during infancy and childhood, with an encouragement and modeling by parental figures of interpersonal withdrawal, indifference, and detachment, could contribute to the development of schizoid personality traits (Bernstein and Travaglini 1999).

Treatment
There have been many studies on the pharmacologic treatment of the STPD but no comparable studies on SZPD (Markovitz 2001, Perry et al. 1999, Soloff 2005). The STPD and SZPD share many features, but the responsiveness of the STPD to pharmacotherapy will usually reflect schizotypal social anxiety and cognitive–perceptual aberrations that are not seen in prototypic, pure cases of SZPD. Prototypic cases of SZPD would rarely present for treatment, whether it is for their schizoid traits or a concomitant Axis I disorder. They would feel little need for treatment, as their isolation will often be ego syntonic. Their social isolation will be of more concern to their relatives, colleagues, or friends than to themselves. Their disinterest in and withdrawal from intimate or intense interpersonal contact will also be a substantial barrier to treatment. They will at times appear depressed but one must be careful not to confuse their anhedonic detachment, withdrawal, and flat affect with symptoms of depression.

If persons with SZPD are seen for treatment for a concomitant Axis I disorder (e.g., a sexual arousal disorder or a substance dependence), it is advisable to work within the confines and limitations of the schizoid personality traits (Beck et al. 1990, Stone 1993). Charismatic, engaging, emotional, or intimate therapists can be very uncomfortable, foreign, and even threatening to persons with SZPD. A more businesslike approach can be more successful (Beck et al. 1990).

It is also important not to presume that persons with SZPD are simply inhibited, shy, or insecure. Such persons are more appropriately diagnosed with AVPD. Persons with SZPD are perhaps best treated with a supportive psychotherapy that emphasizes education and feedback concerning interpersonal skills and communication (Stone 1993). One may not be able to increase the desire for social involvements, but one can increase the ability to relate to, communicate with, and get along with others. Persons with SZPD may not want to develop intimate relationships, but they will...
often want to interact and relate more effectively and comfortably with others. The use of role-playing and videotaped interactions can at times be useful in this respect. Persons with SZPD can have tremendous difficulty understanding how they are perceived by others or how their behavior is unresponsive to and perceived as rejecting by others.

Group therapy is often useful as a setting in which the patient can gradually develop self-disclosure, experience the interest of others, and practice social interactions with immediate and supportive feedback (Piper and Ogrodniczuk 2005). However, persons with SZPD are prone to being rejected by a group due to their detachment, flat affect, and indifference to the feelings of others. If the group is patient and accepting, they can benefit from the experience.

**Schizotypal Personality Disorder**

STPD was a new addition to DSM-III (American Psychiatric Association 1980). It was developed through the process of constructing BPD, both being gleaned from a broad clinical and research literature discussing cases of “borderline schizophrenia,” “borderline personality,” “latent schizophrenia,” and other similar constructs (Spitzer et al. 1979).

**Definition**

STPD is a pervasive pattern of interpersonal deficits, cognitive–perceptual aberrations, and eccentricities of behavior (American Psychiatric Association 2000). The interpersonal deficits are characterized in large part by an acute discomfort with and reduced capacity for close relationships. The symptomatology of STPD has been differentiated further into components of positive (cognitive–perceptual aberrations) and negative (social aversion and withdrawal) symptoms comparable to the distinctions made for schizophrenia (Squires-Wheeler et al. 1997). The presence of STPD is indicated by five or more of the nine diagnostic criteria presented in DSM-IV-TR Criteria 301.22.

**Differential Diagnosis**

AVPD and STPD share the features of social anxiety and introversion, but the social anxiety of STPD does not diminish with familiarity, whereas the anxiety of AVPD is concerned primarily with the initiation of a relationship (Widiger et al. 1995). STPD is also a more severe disorder that includes a variety of cognitive–perceptual aberrations that are not seen in persons with AVPD.

An initial concern of many clinicians when confronted with a person with STPD is whether the more appropriate diagnosis is schizophrenia. Persons with STPD closely resemble persons within the prodromal or residual phases of schizophrenia. This differentiation is determined largely by the absence of a deterioration in functioning. It is indicated in DSM-IV-TR that one should note that STPD is “premorbid” if the schizotypal symptoms were present prior to the onset of schizophrenia (American Psychiatric Association 2000). Premorbid schizotypal traits will have prognostic significance for the course and treatment of schizophrenia, and such traits should then be noted (Siever 1992). However, as discussed for SZPD, in most of these cases the STPD symptoms could then be readily understood as prodromal symptoms of schizophrenia. It should be emphasized, however, that only a very small minority of persons meeting criteria for STPD go on to develop schizophrenia (Raine 2006).

**Epidemiology and Comorbidity**

STPD may occur in as much as 3% of the general population, although most studies with semistructured interviews have suggested a somewhat lower percentage (see Table 82–1). STPD might occur somewhat more often in males (Parnas et al. 2005). STPD co-occurs most often with the schizoid, borderline, avoidant, and paranoid personality disorders (see Table 82–2). Common Axis I disorders are major depressive disorder and generalized social phobia (Miller et al. 2001).
Course
There is insufficient research to describe the childhood precursors of adult STPD, although there are studies on infant and childhood neurodevelopmental abnormalities of persons with STPD (Parnas et al. 2005; Raine 2006). Persons with STPD would be expected to appear peculiar and odd to their peers during adolescence, and may have been teased or ostracized. Achievement in school might be impaired, and they may have been heavily involved in esoteric fantasies and peculiar interests. As adults, they may drift toward esoteric, fringe groups that support their magical thinking and aberrant beliefs. These activities can provide structure for some persons with STPD, but they can also contribute to a further loosening and deterioration if there is an encouragement of aberrant experiences. The symptomatology of STPD does not appear to remit with age (Miller et al. 2001, Raine 2006). The course appears to be relatively stable, with some proportion of schizotypal persons remaining marginally employed, withdrawn, and transient throughout their lives. As noted earlier, some persons meeting DSM-IV-TR criteria for STPD do eventually go on to develop schizophrenia (Walker et al. 2004) but the vast majority of cases do not (Raine 2006). Schizotypal symptomatology, as measured in scales assessing cognitive–perceptual aberrations, magical thinking, and social and physical anhedonia, has been studied longitudinally in a number of community samples, and the findings to date do not suggest any meaningful likelihood of the development of schizophrenia (Gooding et al. 2005).

Etiology and Pathophysiology
There is compelling empirical support for a genetic association of STPD with schizophrenia (Fanous et al. 2001, Jang and Vernon 2001), which is not surprising given that the diagnostic criteria were obtained from the observations of biological relatives of persons with schizophrenia (Miller et al. 2001, Siever and Davis 2004). STPD is in fact classified within the World Health Organization (1992) International Classification as a form of schizophrenia rather than as a personality disorder. Inconsistent with this classification, however, is that STPD is much more comorbid with other personality disorders than with psychotic disorders and schizotypal symptomatology is evident within the general population with no apparent relationship to schizophrenia (Raine 2006).

A predominant model for the psychopathology of STPD is deficits or defects in the attention and selection processes that organize a person’s cognitive–perceptual evaluation of and relatedness to his or her environment (Raine 2006). These defects may lead to discomfort within social situations, misperceptions, and suspicions, and to a coping strategy of social isolation. Correlates of central nervous system dysfunction seen in persons with schizophrenia have been observed in laboratory tests of persons with STPD, including performance on tests of visual and auditory attention (e.g., backward masking and sensory gating tests) and smooth pursuit eye movement (Parnas et al. 2005). This dysfunction may be the result of dysregulation along dopaminergic pathways, which could be serving to modulate the expression of an underlying schizotypal genotype (Raine 2006).

Treatment
Persons with STPD may seek treatment for their feelings of anxiousness, perceptual disturbances, or depression. Treatment of persons with STPD should be cognitive, behavioral, supportive, and/or pharmacologic, as they will often find the intimacy and emotionality of reflective, exploratory psychotherapy to be too stressful and they have the potential for psychotic decompensation.

Persons with STPD will often fail to consider their social isolation and aberrant cognitions and perceptions to be particularly problematic or maladaptive. They may consider themselves to be simply eccentric, creative, or nonconformist. Rapport can be difficult to develop, as increasing familiarity and intimacy may only increase their level of discomfort and anxiety (Siever 1992). They are unlikely to be responsive to informality or playful humor. The sessions should be well structured to avoid loose and tangential ideation.

Practical advice is usually helpful and often necessary (Beck et al. 1990). The therapist should serve as the patient’s counselor, guide, or “auxiliary ego” to more adaptive decisions with respect to everyday problems (e.g., finding an apartment, interviewing for a job, and personal appearance). Persons with STPD should also receive social skills training directed at their awkward and odd behavior, mannerisms, dress, and speech. Specific, concrete discussions on what to expect and do in various social situations (e.g., formal meetings, casual encounters, and dates) should be provided. The rate of progress will tend to be slow, and it

Clinical Vignette 1

LK was a 34-year-old male. He was referred to the Day Hospital Treatment Program by his parents. He had been living with them since his graduation from high school, with no apparent prospects of leaving home. They did not object to his staying at home, but they were now approaching retirement and they were worried that he might not be able to support himself. He was unemployed, had no close friends, and spent much of his time in his room with a computer. LK was first diagnosed with schizotypal personality disorder at the age of 26. The diagnosis was influential in his obtaining of disability income. He had been unemployed since the age of 19. His career goal was to become a successful fortune-teller. He had no history of psychotic episodes, although he had at times become intensely involved in fringe belief systems. The only time he had left home for any significant period was to participate on a quest for a close encounter with an alien in the deserts of Arizona. No concrete, physical encounters occurred, but he did claim to have experienced a variety of signs of alien communication. He was also an active student of “numerology,” or the study of the symbolic and spiritual significance of numbers. He described himself as a “3-8-4.” He did not complain of any clinical symptoms other than chronic feelings of anxiousness, which at times escalated to the point that he felt unable to leave the house. He was also rather odd in his appearance. For example, he would often wear thick red flannel shirts in the summer with lime green pants, and then switch to red pants and a green flannel shirt the next week. He cut his own hair, creating an erratic, peculiar appearance. He described a history of fleeting, superficial relationships. He would at times feel lonely but stated that he found most people to be “discomforting.” (continues)
is helpful if there remains a continuity in the therapeutic relationship (Stone 1993).

Most of the systematic empirical research on the treatment of STPD has been confined to pharmacologic interventions. Low doses of neuroleptic medications (e.g., thiothixene) have shown some effectiveness in the treatment of schizotypal symptoms, particularly the perceptual aberrations and social anxieties (Markovitz 2001, Soloff 2001). Group therapy has also been recommended for persons with STPD but only when the group is highly structured and supportive (Piper and Ogrodniczuk 2005). The emotional intensity and intimacy of unstructured groups will usually be too stressful. Schizotypal patients with predominant paranoid symptoms may even have difficulty in highly structured groups.

Antisocial Personality Disorder

ASPD has been included within every edition of the American Psychiatric Association’s diagnostic manual. It is perhaps the prototypic personality disorder, as the term “psychopathy” originally referred to all cases of personality disorder (Schneider 1923). The term “psychopathy” now refers to a more severe variant of ASPD that predominates much of the current research literature on ASPD (Hare 2003).

Definition

ASPD is a pervasive pattern of disregard for and violation of the rights of others (American Psychiatric Association 2000). Its primary diagnostic criteria include criminal activity, deceitfulness, impulsivity, recklessness, aggressiveness, irresponsibility, and indifference to the mistreatment of others (see DSM-IV-TR Criteria 301.7). DSM-IV-TR ASPD overlaps substantially with psychopathy, as it is assessed by the frequently used Psychopathy Checklist—Revised (PCL-R; Hare 2003). The primary differences are the inclusion of glib charm, arrogance, lack of empathy, and shallow affect within the PCL-R, and the requirement within DSM-IV-TR for evidence of conduct disorder within childhood (Widiger 2005b).

Differential Diagnosis

The PCL-R is a checklist that is particularly well suited for the assessment of this disorder within settings that are heavily populated by persons with a criminal history (e.g., prison and forensic settings), as it includes psychopathic traits that are relatively more specific to ASPD within such settings, such as lack of empathy, glib charm, and arrogance (McDermut and Zimmerman in press, Widiger et al. 2002). The PCL-R, however, may not be used effectively within general clinical settings, as the assessment of much of its items depends heavily on a respondent’s legal record and criminal history (Widiger 2005b).

ASPD will at times be difficult to differentiate from a substance-dependence disorder in young adults because many persons with ASPD develop a substance-related disorder and many persons with a substance dependence engage in antisocial acts. The requirement that the ASPD features be evident prior to the age of 15 though will usually assure the onset of ASPD prior to the onset of a substance-related disorder. If both are evident prior to the age of 15, then it is likely that both disorders are in fact present and both diagnoses should then be made (Widiger 2005b). ASPD and substance dependence will often interact, exacerbating and escalating each other’s development (Sutker and Allain 2001).
Epidemiology and Comorbidity

The National Institute of Mental Health Epidemiologic Catchment Area Study indicated that approximately 3% of males and 1% of females have ASPD (Robins et al. 1991). This rate has been replicated in subsequent studies, but it has also been suggested that the study may have underestimated the prevalence in males due to the failure to consider the full range of ASPD features. Other estimates have been as high as 6% in males (Kessler et al. 1994). The rate of ASPD within prison and forensic settings has been estimated at 50% (Hare 2003, Robins et al. 1991) but the ASPD criteria may exaggerate the rate within such settings due to the emphasis given to overt acts of criminality, delinquency, and irresponsibility that are common to the persons within these settings (Sutker and Allain 2001). More specific criteria for psychopathy provide a more conservative estimate of 20–30% of male prisoners with ASPD (Hare 2003).

ASPD is much more common in men than in women (Robins et al. 1991). A sociobiological explanation for the differential sex prevalence is the presence of a genetic advantage for social irresponsibility, infidelity, superficial charm, and deceit in males that contributes to a higher likelihood of developing features of ASPD (i.e., males with these traits are more likely to have offspring than males without these traits) (Sutker and Allain 2001). Persons with ASPD are likely to display borderline, narcissistic, and paranoid personality traits (see Table 82–2).

Course

ASPD is one personality disorder for which much is known about childhood antecedents, as it is well documented that persons diagnosed with childhood-onset conduct disorder have a considerable risk of meeting the DSM-IV-TR criteria for ASPD as an adult (American Psychiatric Association 2000). The diagnosis of ASPD in fact requires an evidence of conduct disorder in childhood. There are also compelling data to indicate that ASPD is a relatively chronic disorder, although as the person reaches middle to older age research suggests that the frequency of criminal acts appears to decrease. Nevertheless, the core personality traits may remain largely stable (Harpur and Hare 1994).

As adults, persons with ASPD are unlikely to maintain steady employment, and they may even become impoverished, homeless, or spend years within penal institutions (Robins et al. 1991). However, some persons with ASPD characterized by high rather than low levels of conscientiousness may express their psychopathic tendencies within a socially acceptable or at least legitimate profession (Hare 2003). They may in fact be quite successful as long as their tendency to bend or violate the norms or rules of their profession and exploit, deceive, and manipulate others contribute to a career advancement. Their success, however, may at some point unravel when their psychopathic behaviors become problematic or evident to others. The same pattern may also occur within sexual and marital relationships. They may at first appear to be charming, engaging, and sincere, but most relationships will end due to a lack of empathy, responsibility, and fidelity. Persons with ASPD, however, are more likely than the general population to have died prematurely by violent means (e.g., accidents or homicides) and to engage in quite dangerous, high-risk behavior (Sutker and Allain 2001).

Etiology and Pathophysiology

There is considerable support from twin, family, and adoption studies for a genetic contribution to the etiology of the criminal, delinquent tendencies of persons with ASPD (Waldman and Rhee 2006). Exactly what is inherited in ASPD, however, is not known. It could be impulsivity, an antagonistic callousness, or an abnormally low anxiousness, or all of these dispositions combined.

Numerous environmental factors have also been implicated in the etiology of antisocial behavior. Shared, or common, environmental influences account for 15–20% of variation in criminality or delinquency (Rhee and Waldman 2002). Not surprisingly, shared environmental factors such as low family income, inner city residence, poor parental supervision, single-parent households, rearing by antisocial parents, delinquent siblings, parental conflict, harsh discipline, neglect, large family size, and young mother have all been implicated as risk factors for antisocial behavior (Farrington 2006). The effects of these factors are not limited to learning. For instance, neglect and physical abuse can generate several possible avenues to the development of antisocial and aggressive behavior, such as desensitization to pain, impulsive coping styles, and early contact with the justice system (Sutker and Allain 2001). Nonshared environmental influences are also substantial contributors. Factors specific to the individual appear to account for fully 30% of antisocial behavior (Moffitt 2005). In short, this is the remaining variance not accounted for by genetic (50%) or shared environmental (20%) influences. Nonshared environmental factors may include delinquent peers, individual social and academic experiences, or sexual, physical abuse.

Considerable research effort has been focused on trying to isolate the primary pathology of antisocial behavior (Derefenko and Widiger in press). This extensive research base indicates that many deficits are involved in antisocial behavior, leading to a very complex picture of pathology. Historically, the individual with ASPD was said to suffer from a “supernormal lacunae” or deficits of the conscience, later modified in Cleckley’s (1941) and Hare’s (2003) descriptions of “semantic dementia,” or a deficient processing of feelings and emotion. Laboratory research is now providing support for this theoretical model in studies assessing the psychopath’s autonomic reaction to emotional words and fearful images.

The notorious failure of persons with ASPD to accurately anticipate negative consequences has often suggested a psychopathic cognitive deficit (Hiatt and Newman 2006). Existing literature indicates that the psychopathic person experiences stable deficits in the cognitive domains of attention and response modulation. According to this theory, persons with this disorder continue to engage in positively reinforcing behaviors even when they become substantially maladaptive (Newman and Lorenz 2003). Many psychophysiological deficits have also been associated with psychopathy, including an abnormally low physiological response (reduced skin conductance), suggesting that persons with ASPD may not develop the expected anticipatory arousal from threat of physical punishment. Additional autonomic arousal assessments include low resting heart rate levels and startle response deficits (Derefenko and Widiger in press). There is also the suggestion that persons with ASPD may have abnormally low levels of anxiousness. Some distress proneness (neuroticism) and attentional self-regulation
(constraint or conscientiousness) may be necessary in order to develop an adequate sense of guilt or conscience. Normal levels of neuroticism will promote the internalization of a conscience by associating wrongdoing or misbehavior with distress and anxiety, and the temperament of self-regulation will help modulate impulses into socially acceptable channels (Fowles and Kochanska 2000).

**Treatment**

ASPD is considered to be the most difficult personality disorder to treat (Gunderson and Gabbard 2000, Stone 1993). Individuals with ASPD can be seductively charming and declare a commitment to change, but they often lack sufficient motivation. Their declarations of wanting to change might even be dishonest. They often fail to see the costs associated with antisocial acts (e.g., imprisonment, eventual impoverishment, and lack of meaningful interpersonal relationships) and may stay in treatment only as required by an external source, such as a parole. Residential programs that provide a carefully controlled environment of structure and supervision, combined with peer confrontation, have been recommended (Gunderson and Gabbard 2000). However, it is unknown what benefits may be sustained after the ASPD individual leaves this environment. When in inpatient treatment, individuals with ASPD may manipulate and exploit staff and fellow patients (Piper and Ogdroniczuk 2005). Studies have indicated that outpatient therapy is not likely to be successful, although the extent to which persons with ASPD are entirely unresponsive to treatment may have been somewhat exaggerated (Salekin 2001).

**Clinical Vignette 2**

MF was a 24-year-old male, born in Miami, Florida. His biological mother died when he was 3 as the result of a stray bullet during a drug-related dispute. It was unclear whether his mother was herself involved in this dispute. He was taken from his biological father at the age of 6 due to a history of neglect and physical abuse. He then lived in a series of foster homes until the age of 10 when he was adopted by Mr. and Mrs. F.

Mr. and Mrs. F adopted M because they felt too old to raise a child from birth and wished to “give back to society what they had received.” They were quite wealthy and wanted to provide a chance in life for a child from a disadvantaged background. However, they had difficulty from the beginning controlling M. He was first referred to treatment at the age of 13 for setting fire to the school. He was diagnosed with a conduct disorder but was described by his therapist as being fearful, remorseful, and ashamed. Treatment was said to be successful.

At the age of 16 he was remanded to treatment by a juvenile court for assaulting a police officer who had caught him trying to break into a neighbor’s home. Mr. and Mrs. F acknowledged at his court hearing that he had a history of criminal behavior. Since his arrival within their home he had pawned expensive articles from the home and repeated vandalized the house. His parents, however, felt that he simply needed more patience, understanding, and love. They noted that after each “incident” he was always very remorseful. They characterized his various aggressive and criminal acts as “occasional setbacks” or “falling off the wagon.”

Treatment at this time revealed an apparent history of sexual abuse by an older male sibling within one of the foster homes. MF tearfully recounted lurid episodes of sexual victimization and attributed his difficulty controlling his behavior to the abuse he had received from this sibling and his father. Treatment was terminated after 1.5 years of outpatient therapy with no apparent recurrence of criminal or aggressive acts.

MF, however, was again referred to treatment at the age of 24 when he was arrested for attempting to sexually abuse a neighbor’s child. He presented as an intelligent, cultured young man who was ashamed, mortified, and distraught over his “inability” to control his sexual urges. He was diagnosed with pedophilia and referred to both individual and group treatment within a sexual offender’s program. He discussed within his therapies of being sexually abused not only by a foster brother but also by his father.

However, his involvement within the program was questioned when he was discovered at night within the treatment center. He explained that he was simply trying to find his wallet that he left there after one of the group sessions. However, he had no explanation for how he had managed to enter the locked building. He claimed that the entry and office doors had not been locked. Members of his group spoke passionately on his behalf to be allowed to remain within the program. The staff was also painfully ambivalent. On the one hand, he was indeed the result of an abusive and neglectful history; on the other hand, he had committed a serious violation of the treatment program. The decision, however, became easier when it was discovered that he was sexually involved with a member of the staff, another program violation. He had stolen the keys from her. His motivation for treatment was also diminished substantially by the withdrawal of the sexual abuse charges by the neighbor’s child and parents. MF’s parents had apparently interceded on his behalf. The parents, however, continued to insist that he receive some form of treatment. He was then transferred to a summer residential program. After he left the sexual offenders program, group members acknowledged having been intimidated and threatened.

Staff and patients concluded that he was in the building in order to obtain copies of the patients’ confidential files.

The new treatment program was more actively confrontational and less tolerant. He eventually acknowledged that his past claims of being sexually abused were fraudulent. He had been physically abused by his biological father but he had not been sexually abused by him or anyone else. It was also discovered that he had gambled and lost a substantial amount of his parents’ money, and had avoided a series of possible arrests by soliciting and obtaining the support of his parents and sympathetic victims.

MF proved to be very difficult to treat. It was never clear when he was being honestly remorseful and insightful, or simply saying what he believed the staff wanted to hear. His level of intelligence, verbal skills, and engaging charm were very compelling. He was indeed troubled by his past neglect and abuse. He would at times be able to acknowledge the bitterness, anger, and hurt from the past, and yet he would then use whatever sympathy or empathy this history elicited to attempt to manipulate the staff.

When confronted with this disingenuous manipulation he would then confess, express regret and remorse, and attempt a new ploy. None of the staff felt that they were able to develop a really meaningful relationship. He completed the summer program but the staff was pessimistic regarding his future.
Borderline Personality Disorder

BPD was a new edition to DSM-III (American Psychiatric Association 1980, Spitzer et al. 1979) and has since become the single most frequently diagnosed (Gunderson 2001) and studied (Blashfield and Intoccia 2000) personality disorder.

Definition

BPD is a pervasive pattern of impulsivity and instability in interpersonal relationships, affect, and self-image (American Psychiatric Association 2000). Its primary diagnostic criteria include frantic efforts to avoid abandonment, unstable and intense relationships, impulsivity (e.g., substance abuse, binge eating, or sexual promiscuity), recurrent suicidal thoughts and gestures, self-mutilation, and episodes of rage and anger (see DSM-IV-TR Criteria 301.83).

Differential Diagnosis

An instrument that is focused specifically on the assessment of BPD is the Diagnostic Interview for Borderlines—Revised (DIB-R; Zanarini et al. 1989). The DIB-R provides a more thorough assessment of components of BPD (e.g., impulsivity, affective dysregulation, and cognitive-perceptual aberrations) than is provided by more general DSM-IV-TR personality disorder semistructured interviews discussed earlier but psychiatrists might also find it impractical to devote up to 2 hours to assess one particular personality disorder, especially when it is likely that other maladaptive personality traits not covered by the DIB-R are also likely to be present (McDermut and Zimmerman in press, Widiger et al. 2006).

Most persons with BPD develop quite a number of Axis I mental disorders, including mood, dissociative, eating, substance-use, and anxiety disorders (Pfohl 2005). It can be difficult to differentiate BPD from these disorders if the assessment is confined to current symptomatology (Gunderson 2001). The diagnostic criteria for BPD require that the symptomatology be evident since adolescence, which should differentiate BPD from Axis I disorder in all cases other than a chronic mood disorder. If a chronic mood disorder is present, then the additional features of transient, stress-related paranoid ideation, dissociative experiences, impulsivity, and anger dyscontrol of BPD should be emphasized in the diagnosis (Gunderson 2001).

Epidemiology

Approximately 1–2% of the general population would meet the DSM-IV-TR criteria for BPD (see Table 82–1). BPD is the most prevalent personality disorder within most clinical settings. Approximately 15% of all inpatients (51% of inpatients with a personality disorder) and 8% of all outpatients (27% of outpatients with a personality disorder) will have a BPD. Approximately 75% of persons with BPD will be female (Gunderson 2001).

Course

Individuals with BPD are likely to have been emotionally unstable, impulsive, and hostile as children but there is in fact little longitudinal research on the childhood antecedents of BPD (Gunderson 2001, Silk et al. 2005). As adolescents, their intense affectivity and impulsivity may contribute to involvement with rebellious groups, along with a variety of Axis I disorders, including eating, substance, and mood disorders. BPD is at times diagnosed in children and adolescents but considerable caution should be used when doing so, as some of the symptoms of BPD (e.g., identity disturbance, hostility, and unstable relationships) could be confused with a normal adolescent rebellion or identity crisis (Ad-Dab’bagh and Greenfield 2001, Gunderson 2001).
As adults, persons with BPD may be repeatedly hospitalized, due to their affect and impulse dyscontrol, psychotictike and dissociative symptomatology, and suicide attempts (Gunderson 2001, Stone 2005). The risk of suicide is increased with a comorbid mood disorder and substance-related disorder. It is estimated that 3–10% of persons with BPD will have committed suicide by the age of 30 (Gunderson 2001). Intimate relationships tend to be very unstable and explosive, and employment history is generally poor (Stone 2001). As the person reaches the age of 30, affective lability and impulsivity may begin to diminish. These symptoms may lessen earlier if the person becomes involved with a supportive and patient sexual partner (Stone 2001). Some, however, may obtain stability by abandoning the effort to obtain a relationship, opting instead for a lonelier but less volatile life. Occurrence of a severe stressor, however, can easily disrupt the lessening of symptomatology, resulting in a brief psychotic, dissociative, or mood disorder episode.

A controversy within the research literature is the rate of remission of BPD. Some longitudinal studies have provided high rates of remission (Skodol et al. 2005, Zanarini et al. 2005). However, some of these findings may simply represent errors during intake assessments (widiger 2005a). Gunderson et al. (2003) provided details concerning the recent history for many of the persons diagnosed with BPD that were subsequently described as experiencing sudden, dramatic remissions. For one of the participants, the symptoms were attributed to the use of a stimulant for weight reduction during the year prior to the beginning of the study: “The most dramatic improvement following a treatment intervention occurred when a subject discontinued a psycho-stimulant she had used the year prior to baseline for purposes of weight loss...Discontinuation was followed by a dramatic reduction of her depression, panic, abandonment fears, and self-destructiveness” (Gunderson et al. 2003, p 116). The underlying general personality structure of the patients does appear to be relatively more stable (Warner et al. 2004).

Etiology and Pathophysiology

There are studies supportive of BPD as a disorder with a distinct genetic disposition but many studies have also suggested a shared genetic association with mood and impulse control disorders (Torgersen 2005). There is also substantial empirical support for a childhood history of physical and/or sexual abuse, parental conflict, loss, and neglect (Silk et al. 2005). Past traumatic events are present in many (if not most) cases of BPD, contributing to the comorbidity with posttraumatic stress and dissociative disorders (Gunderson 2001, Hefferman and Cloitre 2000). BPD is perhaps best understood as an interaction of an emotionally unstable temperament with a cumulative and evolving series of intensely pathogenic relationships (Gunderson 2001, Widiger 2005d).

The pathogenic mechanisms of BPD are addressed in numerous theories (Stone 2005). Most concern issues of abandonment, separation, and/or exploitative abuse. Persons with BPD will often describe quite intense, disturbed, and/or abusive relationships with the significant persons of their past life (Gunderson 2001). The development of malevolent perceptions and expectations of others is not surprising (Ornduff 2000). These malevolent expectations and lingering feelings of bitterness and rage, along with an impairment in the ability to regulate affect (Chapman and Linehan 2005), may contribute to the perpetuation of intense, hostile, and unstable relationships.

Treatment

Patients with BPD form relationships with therapists that are similar to their other significant relationships; that is, the therapeutic relationship can often be tremendously unstable, intense, and volatile (American Psychiatric Association 2001). Ongoing consultation with colleagues is recommended to address the therapist’s negative reactions toward the client (e.g., distancing, rejecting, or abandoning the patient in response to feelings of anger or frustration) as well as positive reactions (e.g., fantasies of being the therapist who in fact rescues or cures the patient, or romantic, sexual feelings in response to a seductive patient). Sessions should emphasize the building of a strong therapeutic alliance, monitoring of self-destructive and suicidal behaviors, validation of suffering and abusive experience (but also helping the client take responsibility for actions), promotion of self-reflection rather than impulsive action, and setting of limits on self-destructive behavior (Gunderson 2001). The tendency of borderline patients to engage in “splitting” (polarization of an emotional response) should also be carefully monitored and addressed (e.g., devaluation of prior therapists, coupled with idealization of current therapist). The American Psychiatric Association (2001) has published practice guidelines for the psychotherapeutic and pharmacologic treatment of persons with BPD. Because borderline patients can present with significant suicide risk, a thorough evaluation of the potential for suicidal ideation and activity should have the initial priority. Also, many patients with BPD will have comorbid Axis I disorders, some of which might take priority (e.g., major depressive disorder, substance dependence, or dissociative disorder).

Dialectical behavior therapy (DBT; Chapman and Linehan 2005) has been shown empirically to be a particularly effective treatment of BPD (Lynch et al. 2007). The American Psychiatric Association (2001) also concluded that psychodynamic psychotherapy has obtained empirical support for the treatment of BPD that is equal to DBT (Bateman 2005, Gabbard 2000b), although this conclusion has been disputed (Sanderson et al. 2002). The dialectical component of DBT was derived largely from Zen Buddhist principles of overcoming suffering through acceptance. Mastery of conflict is achieved in part through no longer struggling or fighting adversity; pain is overcome when it is accepted as an inevitable, fundamental part of life. This principle is taught in part through the meditative technique of mindfulness, in which one attempts to empty one’s mind of all thoughts, but accepts whenever and wherever the mind naturally travels. DBT initially focuses on reducing self-harm and parasuicidal behaviors that are disruptive to treatment. Contracts are at times used in which time with the therapist is limited secondary to treatment disruptive behavior. This can even go so far as to include suspension of treatment secondary to suicidal behavior. After mastery of treatment disruptive behavior, DBT teaches coping skills focused on emotional control and interpersonal relatedness. Individuals in DBT attend regular sessions with an individual therapist and discuss problems in applying the new skills. These sessions are augmented with a didactic skills-training group. Tables 82-4 and 82-5 provide a list of DBT treatment principles.

### Basic Propositions of BPD Treatment from DBT

1. Patients are doing the best they can
2. Patients want to improve
3. Patients need to do better, try harder, and be more motivated to change
4. Patients may not have caused all of their own problems, but they have to solve them anyway
5. The lives of suicidal, borderline individuals are unbearable as they are currently being lived
6. Patients must learn new behaviors in all relevant contexts
7. Patients cannot fail in therapy
8. Therapists treating borderline patients need support

### Clinical Vignette 3

SC was a 36-year-old female. She was referred to a Day Hospital Borderline Personality Disorders Treatment Program after her fourth hospitalization for depression and suicidality. SC had not known her father. She was raised by her mother who had a polysubstance dependence. Her relationship with her mother was described as negligent and distant. She had two brothers. The oldest brother abused her sexually for 3 years since she was 13 years old. The abuse ended when he was drafted into the army. She denied any feelings of anger or bitterness to him, and in fact described substantial feelings of fondness and affection. He died while serving in Vietnam.

She obtained good to excellent grades in school but had a history of indiscriminate sexual behavior, substance abuse, and bulimia. (Her common method for purging was to attempt to swallow a belt, thereby inducing vomiting.) Her first treatment was at the age of 19. She became significantly depressed when she discovered that her fiancé was sexually involved with her best friend. Her hospitalization was precipitated by the ingestion of a lethal amount of drugs. Subsequent to this hospitalization she began to mutilate herself by scratching or cutting her arms with broken plates, dinner knives, or metal. The self-mutilation was usually precipitated by episodes of severe loneliness and feelings of emptiness.

She had a very active social life and a large network of friends. However, her relationships were very unstable. She could be quite supportive, engaging, and personable, but would overreact to common conflicts, disagreements, and difficulties. She would feel intensely hurt, depressed, angry, or enraged, and would hope that her friends would relieve her pain through some gesture. However, they would typically feel frustrated, annoyed, or overwhelmed by the intensity of her affect and her reactions.

Her sexual relationships were even more problematic. She would quickly develop intense feelings of attraction, involvement, and dependency. However, she would soon experience her lovers as disappointing and neglectful, which at times had more than a kernel of truth. Many were neglectful, unempathic, or abusive, but all of them found the intensity of the inevitable conflicts and her anger to be intolerable.

She was also questioning her sexual orientation. She had never been sexually involved with a woman, but she did have fantasies of an involvement with various women that she had known. It was conceivable that she might find a relationship with a woman to be more stable and satisfying, but it was likely that as much conflict would occur with women as had occurred with men.

She attended the Day Hospital BPD Program for 2 years. Treatment included group therapy, individual psychotherapy (using both cognitive–behavioral and insight), and antidepressant medication. The cognitive–behavioral treatment focused on daily management of problems, exploring alternative perceptions of means for addressing conflicts with others, and gradually developing more effective coping strategies. The irrationality of her reactions became more apparent to her as their source within her past relationships was better understood. Treatment was successful in ending her reliance on self-mutilation and in decreasing the intensity of her interpersonal conflicts. She continued to have unstable relationships, but she was much more successful in acknowledging and resolving conflicts in ways that were more realistic and appropriate.

Pharmacologic treatment of patients with BPD is varied, as it depends primarily on the predominant Axis I symptomatology (Markovitz 2001, Soloff 2005). Persons with BPD can display a wide variety of Axis I symptoms, including anxiety, depression, hallucinations, delusions, and dissociations. It is important in their pharmacologic treatment not to be unduly influenced by transient symptoms or by symptoms that are readily addressed through exploratory or supportive techniques. On the other hand, it is equally important to be flexible in the use of medications and not to be unduly resistant to their use. Relying solely upon one’s own psychotherapeutic skills can be unnecessary and even irresponsible.

### Histrionic Personality Disorder

HPD was not included within the first edition of the American Psychiatric Association’s diagnostic manual. It was introduced in DSM-II (American Psychiatric Association 1968) and is perhaps one of the more controversial of the personality disorder diagnoses, given its close association with stereotypic feminine traits (Kaplan 1983, Ross et al. 1995, Widiger and First in press).
Definition
HPD is a pervasive pattern of excessive emotionality and attention seeking (American Psychiatric Association 2000). Histrionic persons tend to be emotionally manipulative and intolerant of delayed gratification (Bornstein 1999, Stone 2005). HPD is indicated by the presence of five or more of the eight diagnostic criteria presented in DSM-IV-TR Criteria 301.50.

Differential Diagnosis
HPD involves to some extent maladaptive variants of stereotypically feminine traits (Kaplan 1983). The DSM-IV-TR diagnostic criteria for HPD are sufficiently severe that a normal woman would not qualify, but studies have indicated that women are at times over diagnosed with the disorder (Widiger and First in press). Some self-report inventories are particularly prone to gender-biased assessments of HPD (Lindsay et al. 2000). It is therefore important to adhere closely to the DSM-IV-TR diagnostic criteria when confronted with histrionic symptoms in female patients.

Persons with HPD will often have borderline, dependent, or narcissistic personality traits (see Table 82–2). Prototypic cases of HPD can be distinguished from other personality disorders (Widiger et al. 1995). For example, the prototypic narcissistic person ultimately desires admiration, whereas the histrionic person desires whatever attention, interest, or concern can be obtained. As a result, the histrionic person will at times seek attention through melodramatic helplessness and emotional outbursts that could be experienced as denigrating and humiliating to the narcissistic person. However, most cases will not be prototypic and the most accurate description of a patient’s constellation of maladaptive personality traits will be the provision of multiple diagnoses (Widiger and Trull 2007).

Epidemiology and Comorbidity
Approximately 1–3% of the general population may be diagnosed with HPD (see Table 82–1; Mattia and Zimmerman 2001, Torgersen et al. 2001). A controversial issue is its differential sex prevalence (Bornstein 1999, Stone 2005, Widiger and First in press). It is stated in DSM-IV-TR that the sex ratio for HPD is “not significantly different than the sex ratio of females within the respective clinical setting” (American Psychiatric Association 2000, p 712). However, this should not be interpreted as indicating that the prevalence is the same for males and females. It has typically been found that at least two thirds of persons with HPD are female, although there have been a few exceptions (Corbitt and Widiger 1995). Whether or not the rate will be significantly higher than the rate of women within a particular clinical setting depends upon many factors that are independent of the differential sex prevalence for HPD (Widiger 1998).

Course
Little is known about the premorbid behavior pattern of persons with HPD (Bornstein 1999, Stone 2005). During adolescence they are likely to have been flamboyant, flirtatious, and attention seeking. As adults, persons with HPD will readily form new relationships but will have difficulty sustaining them. They may fall in love quite quickly, but just as rapidly become attracted to another person. They are unlikely to be reliable or responsible. Relationships with persons of the same sexual orientation will often be strained due to their competitive sexual flirtatiousness. Employment history is likely to be erratic and may be complicated by the tendency to become romantically or sexually involved with colleagues, by their affective instability, and by their suggestibility. Persons with HPD may become devoted converts to faddish belief systems. They have a tendency to make impulsive decisions that will have a dramatic (or melodramatic) effect on their lives. The severity of the symptomatology may diminish somewhat as the person ages.

Etiology and Pathophysiology
There is little research on the etiology of HPD (Blashfield and Intoccia 2000, Stone 2005). There is a suggestion that HPD may share a genetic disposition toward impulsivity or sensation seeking with the ASPD (Lilienfeld and Hess 2001). It has also been suggested that HPD is (in part) a severe, maladaptive variant of the personality dimensions of extraversion and neuroticism (Widiger et al. 2002). Extraversion includes a disposition toward excitement seeking, gregariousness, and positive emotionality; and neuroticism includes the facets of angry hostility, self-consciousness, and vulnerability (Costa and McCrae 1992). There is considerable empirical support for the heritability of these personality dimensions (Bouchard and Loehlin 2001, Widiger and Trull 2007).

Environmental and social–cultural factors, however, may also play a significant role in the development of HPD.
Affective instability is an important feature of HPD, which may be associated with a hyperresponsiveness of the noradrenergic system. This instability in the catecholamine functioning may contribute to a pronounced emotional reactivity to rejection and loss (Markovitz 2001). However, the attention seeking of HPD can be as important to the disorder as the emotionality. The purpose of the exaggerated emotionality is often to evoke the attention and maintain the interest of others (Bornstein 1999, Gunderson and Gabbard 2000, Stone 1993). Persons with HPD are intensely insecure regarding the extent to which others appreciate, desire, or want their company. They need to be the center of attention to reassure themselves that they are valued, desired, attractive, or wanted.

### Treatment

Persons with HPD will readily develop rapport but it will often be superficial and unreliable (Stone 2005). Therapists might also fail to appreciate the extent of influence they can have on the highly suggestible HPD patient (Bornstein 1999). Persons with HPD can readily become converts to whatever the therapist may suggest or encourage. The transformation to the theoretical model or belief system of the psychiatrist is unlikely to be sustained.

A key task in treating the patients with HPD is countering their global and diffuse cognitive style by insisting on attending to structure and detail within sessions and to the practical, immediate problems within daily life (Beck et al. 1990, Gunderson and Gabbard 2000, Stone 1993). It is also important to explore within treatment the historical source for their need for attention and involvement. Persons with HPD are prone to superficial and transient insights but they will benefit from a carefully reasoned and documented exploration of their current and past relationships.

Many clinicians recommend the use of group therapy for persons with HPD (Beck et al. 1990, Gabbard 2000a, Millon et al. 1996, Piper and Ogrodniczuk 2005). It is quite easy for them to become involved within a group, which may then be very useful in helping them recognize and explore their attention seeking, suggestibility, and manipulation, as well as develop alternative ways to develop more meaningful and sustained relationships. However, it is also important to closely monitor their involvements within the group, as they are prone to dominate and control sessions and they may escalate their attention seeking to the point of suicidal gestures. The intense affectivity of persons with HPD may also be responsive to antidepressant treatment, particularly those patients with substantial mood reactivity, hypersomnia, and rejection sensitivity (Markovitz 2001, Soloff 2005).

### Narcissistic Personality Disorder

NPD was new to the third edition of the American Psychiatric Association (1980) diagnostic manual. Its inclusion “was suggested by an increasing psychoanalytic literature and by the isolation of narcissism as a personality factor in a variety of psychological studies” (Frances 1980, p 1053). However, it is still not included within the World Health Organization (1992) International Classification of Diseases despite its presence since 1980 within DSM-III, as it has been perceived internationally as largely an American concept (Ronningstam 2005).

#### Definition

NPD is a pervasive pattern of grandiosity, need for admiration, and lack of empathy (American Psychiatric Association 2000). Persons with NPD can be very vulnerable to threats to their self-esteem. They may react defensively with rage, disdain, or indifference but are in fact struggling with feelings of shock, humiliation, and shame. NPD is indicated by the presence of five or more of the nine diagnostic criteria presented in DSM-IV-TR Criteria 301.81.

#### DSM-IV-TR Criteria 301.81

Narcissistic Personality Disorder

A. A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)

2. is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love

3. believes that he or she is “special” and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)

4. requires excessive admiration

5. has a sense of entitlement, i.e. unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations

6. is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends

7. lacks empathy: is unwilling to recognize or identify with the feelings and needs of others

8. is often envious of others or believes that others are envious of him or her

9. shows arrogant, haughty behaviors or attitudes

Differential Diagnosis
NPD overlaps substantially with ASPD and particularly its more severe variant, psychopathy. Kernberg (1998) considers the ASPD and NPD to lie along a common continuum of psychopathology. Both disorders include a disposition to dominate, humiliate, and manipulate others. Stone (1993) goes so far as to suggest, “all psychopathic persons are at the same time narcissistic persons” (Stone 1993, p 292). Hart and Hare (1998), psychopathy researchers, suggest alternatively, “psychopathy can be viewed as a higher-order construct with two distinct, albeit related facets, one of which is very similar to the clinical concept of narcissism” (p 429).

To help differentiate the NPD and ASPD, it has been suggested that “narcissists are usually more grandiose, while ASPD patients are exploitative, have a superficial value system, and are involved in recurrent antisocial activities” (Ronnningstam 1999, p 681). It is also suggested that “exploitiveness in antisocial patients is probably more likely to be consciously and actively related to materialistic or sexual gain, while exploitive behavior in narcissistic patients is more passive, serving to enhance self-image by attaining praise or power” (Ronnningstam 1999, p 681). Kernberg suggests, “the way to differentiate…narcissistic personality disorder from an antisocial personality disorder proper is the absence in the latter of the capacity for feeling guilt and remorse” (Kernberg 1998, pp 42–43). Narcissistic persons will feel guilty and remorseful when confronted with the negative effects of their exploitative use of others, whereas antisocial persons will not (Widiger et al. 1995). These speculations are compelling and have perhaps been beneficial in clinical practice, but they have not yet been empirically evaluated.

Epidemiology and Comorbidity
NPD is among the least frequently diagnosed personality disorders within clinical settings (Gunderson et al. 1991), with estimates of prevalence as low as 2% (American Psychiatric Association 2000). A curious finding is that many community studies that have used a semistructured interview have not even been able to identify one single case (see Table 82–1), despite the substantial amount of research on maladaptive narcissistic personality traits within normal community and college samples (Morf and Rhodewalt 2001, Ronningstam 2005). It may be that the DSM-IV-TR diagnostic criteria do not fully capture the essential features of NPD (Gunderson et al. 1991). DSM-IV-TR NPD is diagnosed more frequently in males (American Psychiatric Association 2000), consistent with the finding within general personality research that men tend to be, on average, more arrogant than women (Costa et al. 2001). Persons with NPD are considered to be prone to mood disorders, as well as anorexia and substance-related disorders, especially cocaine (American Psychiatric Association 2000, Ronningstam 2005). Persons with NPD are likely to have comorbid antisocial (psychopathic), hysterionic, paranoid, and borderline personality traits (see Table 82–2).

Course
Little is known empirically about the course of narcissism. Clinical experience suggests that this disorder does not abate with age and may even become more evident into middle or older age (Kernberg 2004a). Persons with this disorder might be seemingly well adjusted and even successful as a young adult, having experienced substantial achievements in education, career, and perhaps even within relationships (Ronningstam 2005). However, their relationships with their colleagues, peers, and intimates might become strained over time as their lack of consideration for and even exploitative use of others becomes cumulatively evident. Successes might also become more infrequent, as their inability to accurately perceive or address criticism and setback contributes to a mounting number of failures. Persons with this disorder may at times not recognize their pathology until they have had a substantial number of setbacks, or they have finally recognized that the excessive importance they have given to achievement, success, and status has led to an emptiness and loneliness in their older age (Stone 1993). As a result, midlife and late-life transitions may be particularly difficult for persons with this disorder.

Etiology and Pathophysiology
There has been little systematic research on the etiology of narcissism. Two twin studies have supported heritability for narcissistic personality traits (Jang et al. 1996, Torgersen et al. 2000), although given the complexity of narcissism (Fossati et al. 2005, Morf and Rhodewalt 2001, Raskin and Terry 1988, Ronningstam 2005), it is not entirely clear what precisely is being inherited. The predominant models for the etiology of narcissism have been largely social learning or psychodynamic (Ronningstam 2005). One model proposes that narcissism develops through an excessive idealization by parental figures, which is then incorporated by the child into his or her self-image (Millon et al. 1996). Narcissism may also develop through unempathic, neglectful, inconsistent, or even devaluing parental figures who have failed to adequately mirror a child’s natural need for idealization (Kohut 1977). The child may find that the attention, interest, and perceived love of a parent are contingent largely on achievements or successes. They may fail to perceive the parents as valuing or loving them for their own sake, but may instead recognize that the love and attention are largely conditional on successful accomplishments. They might then develop the belief that their own feelings of self-worth are dependent upon a continued recognition of such achievements, status, or success by others. The character armor of arrogant self-confidence then masks a vulnerability and at times robs the feeling of having been so neglected, and perhaps even mistreated and denigrated, as a child.

Conflicts and deficits with respect to self-esteem are central to the pathology of the disorder (Kernberg 1998, 2004a, Ronningstam 2005, Stone 1993), and there is considerable empirical support for this pathology in studies published within the general personality literature (Morf and Rhodewalt 2001). Narcissistic persons must continually seek and obtain signs and symbols of recognition to compensate for conscious or perhaps even unconscious feelings of inadequacy. Narcissism is not simply arrogant self-confidence, as it is more highly correlated with an instability in self-esteem rather than a consistently high self-confidence. Their feelings of insecurity will at times be evident but may also be masked by a disdainful indifference to criticism or even by overt expressions of anger and rage (Baumeister et al. 1996). Narcissistic persons may at times claim that it is not narcissism if they are in fact brilliant, talented, and successful. However, the pathology would still be evident by the excessive need for
Treatment

Persons rarely seek treatment for their narcissism. Individuals with NPD enter treatment-seeking assistance for another mental disorder, such as substance abuse (secondary to career stress), mood disorder (secondary to career setback), or even something quite specific, such as test anxiety. One may at times have narcissistic persons seeking treatment for a growing sense of discontent and futility with their lives (Ronningstam 2005). Once an individual with NPD is in treatment, he or she will have difficulty perceiving the relationship as collaborative and will likely attempt to dominate, impress, or devalue the therapist. They can idealize their therapists (to affirm that he or she is indeed of sufficient status or quality) but they may also devalue their therapist to affirm that they are of greater intelligence, capability, or quality, to reject the insights that they have failed to identify themselves, and to indicate that they warrant or deserve an even better therapist. How best to respond is often unclear as the establishment and maintenance of rapport will be an early and ongoing issue. It may at times be preferable to simply accept the praise or criticism, particularly when exploration will likely be unsuccessful, whereas at other times it is preferable to confront and discuss the motivation for the devaluation (or the idealization).

The optimal response to a narcissist’s idealization has been a significant controversy within the psychoanalytic literature (Gabbard 2000a). Kohut (1977) had generally recommended a provision of empathy and a reflection (or mirroring) of positive regard and self-esteem, whereas Kernberg (2004b) generally recommended active confrontation of idealization, as early idealization would inevitably be followed by devaluation. Cognitive–behavioral approaches to NPD emphasize increasing awareness of the impact of narcissistic behaviors and statements on interpersonal relationships (Beck et al. 1990, Young et al. 2003). The idealization and devaluation can be responsive to role-playing and rational introspection, an intellectual approach that may itself be valued by some persons with NPD. Therapists must be careful not to become embroiled within intellectual conflicts and the recognition of their achievements. They are uncomfortable when they are not being adequately appreciated for their accomplishments and they may in fact feel grossly insulted or enraged when they feel unjustly slighted (Stone 1993).

Clinical Vignette 4

RP was a well-regarded clinician with a good publication record and a successful private practice. However, one of his patients filed a complaint with the state board after their sexual relationship ended. He offered in his defense that his behavior was simply the result of marital stress. His license to practice was suspended indefinitely. One of the terms of his probation was to successfully complete 2 years of psychotherapy. RP agreed that treatment would be beneficial but questioned whether any clinician within his local community was sufficiently qualified, as he considered himself to be among the leading clinicians within this community.

Treatment was problematic from the very beginning. RP felt that their discussions should be quid pro quo: if he was going to reveal aspects of himself then the therapist should do likewise. When confronted with the understanding that he was the one in treatment, RP argued that the therapist must be having “narcissistic conflicts” if he is unwilling to accept the insight and guidance that he could offer. Some of the difficulty within the treatment was attributable to the situation (i.e., it would probably be difficult for most therapists to be mandated to receive therapy from a colleague) but as treatment progressed it became apparent that he had similar conflicts with other persons in his life.

RP’s wife was threatening divorce in part because of a history of extramarital affairs. RP did not deny the existence of these affairs, but argued that his wife was exaggerating their importance: the other women meant little to him, why should they be of concern to her? He said that he did not keep his affairs secret from her prior to marriage (at least those that he was unable to keep secret), and therefore she knew from the beginning that extramarital affairs would occur. In addition, he felt that his affairs were only petty philandering and that his wife should tolerate them because she was “frankly lucky” to have him for a husband. He was good looking, wealthy, and professionally successful, and felt that if he had been more patient he might have found someone better than her.

RP was popular with women, at least at the beginning of relationships. He was charming, engaging, and verbally facile. However, he acknowledged during the course of therapy that some women eventually became unhappy, dissatisfied, and at times even angry with him. It is quite possible that his perception of his past relationships even understated the extent of the dissatisfaction. He attributed their dissatisfaction to “unrealistic and neurotic expectations.” He stated that women would flirt with him because he is an “attractive catch” and that he was only fulfilling their fantasies by letting them become involved with him. He would soon lose interest though in the women with whom he became involved, and he acknowledged that it was not always easy to extricate himself from a relationship without any cost to himself.

He evidenced only a marginal insight into the potential harm he had caused the patient with whom he had the sexual relationship. He argued that the proscription against sexual involvements should not have been enforced in this instance because he had been very careful in determining that their relationship was not the intended target of the ethical guidelines: she was herself a “competent” professional who had “freely” entered the relationship and, in any case, no complaint would have been filed if he had been willing to continue the relationship. She was a well-known public figure. She testified to the state board that he repeatedly suggested to her that she accompany him on his business trips, and it was her impression that he wanted to show her off as a “trophy” to his colleagues. She stated that she ended the relationship when she discovered from her colleagues that he was bragging to others about their relationship and revealing details of their sexual activities.

Treatment was terminated by RP after 6 months of treatment upon reading the biannual report by his therapist to the state board regarding his progress. RP felt that he had been making substantial progress that was not being adequately appreciated by his therapist. He noted, for example, that his wife was no longer seeking a divorce and that his ex-patient was engaged to be married. He did indicate that he was dissatisfied with treatment, and felt that progress would be improved by “a more experienced and respected” clinician. He attributed the therapist’s negative evaluation of his progress to professional jealousy.

Chapter 82 • Personality Disorders 1739
competitions. Narcissistic persons can be acutely aware of the self-esteem conflicts of their therapist, and it is best for the therapist to model a comfortable indifference to losing disputes or conflicts.

Group therapy can be useful for increasing awareness of the grandiosity, lack of empathy, and devaluation of others (Piper and Ogrodniczuk 2005). However, these traits not only interfere with the narcissistic person’s ability to sustain membership within groups (and within individual therapy), they may also become quite harmful and destructive to the rapport of the entire group. There is no accepted pharmacologic approach to the treatment of narcissism (Markovitz 2001, Soloff 2005).

Avoidant Personality Disorder
AVPD was a new addition to DSM-III (American Psychiatric Association 1980). A criticism of its inclusion was that it had little prior recognition within the personality disorder literature (Gunderson 1983). However, it is now one of the more frequently diagnosed personality disorders (see Table 82–1), as timid, anxious, and insecure introversion is a common social and clinical problem (Millon et al. 1996).

Definition
AVPD is a pervasive pattern of timidity, inhibition, inadequacy, and social hypersensitivity (American Psychiatric Association 2000). Persons with AVPD may have a strong desire to develop close, personal relationships but feel too insecure to approach others or to express their feelings. AVPD is indicated by the presence of four or more of the seven diagnostic criteria presented in DSM-IV-TR Criteria 301.82.

Differential Diagnosis
The most difficult differential diagnosis for AVPD is with generalized social phobia (Ralevski et al. 2005, Tillfors et al. 2004, Widiger 2005c). Both involve an avoidance of social situations, social anxiety, and timidity, and both are said to emerge from a childhood of shyness and introversion (American Psychiatric Association 2000). There is perhaps no meaningful distinction between them, as acknowledged in DSM-IV-TR. There are arguments to subsume all cases of AVPD into the diagnosis of generalized social phobia (First et al. 2002), as was done for introverted schizoid disorder of childhood in DSM-IV-TR. Support for the annexation of AVPD within generalized social phobia comes in part from the suggestion that insurance coverage will be easier to obtain for the treatment of an anxiety disorder than a personality disorder (Widiger 2005c). However, there is also considerable empirical support for the genetics, the neurophysiology, the childhood antecedents, the temporal stability, and the universality of the personality dimensions of introversion and neuroticism (Allik 2005, Bouchard and Loehlin 2001, Caspi et al. 2005, Depue and Lenzenweger 2001, Roberts and DelVecchio 2000).

Many persons with AVPD may also meet the criteria for DPD. This might at first glance seem unusual, given that AVPD involves social withdrawal whereas DPD involves excessive social attachment. However, once a person with AVPD is able to obtain a relationship, he or she will often cling to this relationship in a dependent manner. Both disorders include feelings of inadequacy, needs for reassurance, and hypersensitivity to criticism and neglect (i.e., abnormally high levels of anxiousness, self-consciousness, and vulnerability). A distinction between AVPD and DPD is best made when the person is seeking a relationship (Widiger et al. 1995). Avoidant persons tend to be very shy, inhibited, and timid (and are therefore slow to get involved with someone), whereas dependent persons urgently seek another relationship as soon as one ends (i.e., avoidant persons are high in introversion, whereas dependent persons are high in extraversion). Avoidant persons may also be reluctant to express their feelings, whereas dependent persons can drive others away by continuous expressions of neediness. The differentiation of AVPD from the SZPD and STPD was discussed in previous sections.

Epidemiology and Comorbidity
Timidity, shyness, and social insecurity are not uncommon problems (Crozier and Alden 2005) and AVPD is one of the more prevalent personality disorders within clinical settings, occurring in 5–25% of all patients (American Psychiatric Association 2000, Mattia and Zimmerman 2001). However, AVPD may be diagnosed in only 1–2% of the general population (see Table 82–1). It appears to occur equally among males and females, with some studies reporting more males and others reporting more females (Corbitt and Widiger 1995). Persons with AVPD are likely to have symptoms that meet the DSM-IV-TR criteria for a generalized social phobia, and others may have a mood disorder.

---

**AVOIDANT PERSONALITY DISORDER**

A. A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection

2. is unwilling to get involved with people unless certain of being liked

3. shows restraint within intimate relationships because of the fear of being shamed or ridiculed

4. is preoccupied with thoughts of being criticized or rejected in social situations

5. is inhibited in new interpersonal situations because of feelings of inadequacy

6. views self as socially inept, personally unappealing, or inferior to others

7. is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

---

Course

Persons with AVPD will have been shy, timid, and anxious as children (Bernstein and Travaglini 1999, Millon et al. 1996). Some will have been diagnosed with a social phobia during childhood. Adolescence will have been a particularly difficult developmental period, due to the importance at this time of attractiveness, dating, and popularity. Occupational success may not be significantly impaired, as long as there is little demand for public performance. Persons with AVPD may in fact find considerable gratification and esteem through a job or career that they are unable to find within their relationships. The job may serve as a distraction from intense feelings of loneliness. Their avoidance of social situations will impair their ability to develop adequate social skills, and this will then further handicap any eventual efforts to develop relationships. As parents, they may be very responsible, empathic, and affectionate, but may unwittingly impart feelings of social anxiety and awkwardness. Severity of the AVPD symptomatology diminishes as the person becomes older.

Etiology and Pathophysiology

There is limited research on the etiology or pathology of DSM-IV-TR AVPD. However, AVPD is well understood as an extreme variant of the fundamental personality traits of introversion and neuroticism (Tyrer 2005, Widiger et al. 2002). Introversion includes such facets as passivity, social withdrawal, and inhibition, and neuroticism includes self-consciousness, vulnerability, and anxiety (Costa and McCrae 1992). There is considerable empirical support for the etiology of these personality dimensions (McCrae and Costa 1999).

In childhood, neuroticism appears as a distress-prone or inhibited temperament (Rothbart et al. 2000). Shyness, timidity, and interpersonal insecurity might be exacerbated further in childhood through overprotection and excessive cautiousness (Schmidt et al. 2001). Parental behavior coupled with a distress-prone temperament has been shown to result in social inhibition and timidity (Burgess et al. 2001). Most children and adolescents will have many experiences of interpersonal embarrassment, rejection, or humiliation, but these will be particularly devastating to the person who is already lacking in self-confidence or is temperamentally passive, inhibited, or self-conscious.

AVPD may involve elevated peripheral sympathetic activity and adrenocortical responsiveness, resulting in excessive autonomic arousal, fearfulness, and inhibition (Siever and Davis 1991). Just as ASPD may involve deficits in the functioning of a behavioral inhibition system, AVPD may involve excessive functioning of this same system (Depue and Lenzenweger 2001). The pathology of AVPD, however, may be as much psychological as neurochemical, with the timidity, shyness, and insecurity being a natural result of a cumulative history of denigrating, embarrassing, and devaluing experiences (Schmidt et al. 2001). Underlying AVPD may be excessive self-consciousness, feelings of inadequacy or inferiority, and irrational cognitive schemas that perpetuate introverted, avoidant behavior (Beck et al. 1990).

Treatment

Persons with AVPD will seek treatment for their avoidant personality traits, although many will initially seek treatment for symptoms of anxiety, particularly social phobia (generalized subtype). It is important in such cases to recognize that the shyness is not due simply to a dysregulation or dyscontrol of anxiousness. There is instead a more pervasive and fundamental psychopathology, involving feelings of interpersonal insecurity, low self-esteem, and inadequacy (Millon et al. 1996, Paris 1998, Stone 1993, Widiger 2001).

Social skills training, systematic desensitization, and a graded hierarchy of in vivo exposure to feared social situations have been shown to be useful in the treatment of AVPD (Beck et al. 1990, Millon et al. 1996). However, it is also important to discuss the underlying fears and insecurities regarding attractiveness, desirability, rejection, or intimacy (Gabbard 2000a, Gunderson and Gabbard 2000, Stone 1993). Persons with AVPD will at times be reluctant to discuss such feelings, as they may feel embarrassed, they may fear being ridiculed, or they may not want to “waste the time” of the therapist with such “foolish” insecurities. They may prefer a less revealing or involved form of treatment. It is important to be understanding, patient, and accepting, and to proceed at a pace that is comfortable for the patient. Insecurities and fears can at times be addressed through cognitive techniques, as the irrationality is usually readily apparent (Beck et al. 1990). It remains useful though to identify the historical source of their development, as this understanding will help the patient appreciate the irrationality or irrelevance of the patient’s expectations and perceptions for his or her current relationships.

Persons with AVPD will often find group therapies to be helpful (Piper and Ogrodniczuk 2005). Exploratory and supportive groups can provide them with an understanding environment in which to discuss their social insecurities, to explore and practice more assertive behaviors, and to develop an increased self-confidence to approach others and to develop relationships outside of the group. Focused and specialized social-skills-training groups would be preferable to unstructured groups that might be predominated by much more assertive and extraverted members.

Many persons with AVPD will respond to anxiolytic medications and at times to antidepressants, particularly such monoamine oxidase inhibitors as phenelzine (Markovitz 2001, Soloff 2005). Normal and abnormal feelings of anxiousness can be suppressed or diminished through pharmacologic interventions (Widiger 2005c). This approach may in fact be necessary to overcome initial feelings of intense social anxiety that are markedly disruptive to current functioning (e.g., inability to give required presentations at work or to talk to new acquaintances). However, it is also important to closely monitor a reliance on medications. Persons with AVPD could be prone to rely excessively on substances to control their feelings of anxiousness, whereas their more

Clinical Vignette 5

LW was a 26-year-old female. She was first seen in treatment at the age of 19 when she entered an anxiety disorders treatment program. She was a music major (specializing in the flute) at a prominent university. However, she suffered from substantial feelings of anxiety to the point that she was unable to perform in front of an audience. She was diagnosed with a generalized social phobia when it was discovered that she was anxious within a wide variety of other social situations. She was generally timid, insecure, shy, and introverted. She was treated with phenelzine, and (continues)
found substantial improvement within a few weeks in her more severe feelings of anxiety. She was able to complete the music program and graduated with honors.

However, she subsequently sought outpatient therapy at the age of 23 for feelings of depression. She complained of substantial feelings of inadequacy, worthlessness, and helplessness. She was currently married to a man who was sexually abusive and emotionally detached. She had in fact been involved in a series of disappointing and often exploitative relationships. She described herself as being undesirable, and yet she was in fact bright, attractive, responsible, and affectionate. Her past boyfriends had been either socially inadequate or domineering males who failed to provide her with much emotional support or meaningful involvement. Her current husband was attractive to her primarily because she perceived him as successful, strong, and protective. However, he was also continually critical, derogatory, and often required her to perform sexual acts that she found humiliating.

Her employment history was equally disappointing. She would rarely apply for any quality employment because she assumed that she would be rejected. When she did find employment, she would quit within just a few weeks because of feelings of tension and anxiety. Her feelings of anxiety were not confined to performing in front of others. She described a terror over the thought of disappointing any employer. She was in fact very capable, responsible, and even talented, but she was certain that she would eventually be shown to be inadequate and incompetent.

She described her mother as having been continually anxious and nervous, with a history of depression in her biological relatives. She described her father as being alcoholic, derogatory, and hostile. A typical example of his emotional abuse consisted of him interrogating at dinner each sibling in turn regarding his or her behavior (or failures) that day. Those that met with his disapproval were sent from the table. He performed very well in school because she was intensely afraid of his anger if she did less than excellent. She was cognitively aware that his criticisms were usually inappropriate and always excessive, but she could not help feeling fearful and hurt. He was her father and how he felt about her meant a great deal to her. In fact, she had largely incorporated his attitude to her as her own attitude toward herself.

She was treated with an antidepressant, group therapy for interpersonal assertiveness, and 3 years of outpatient psychotherapy that focused on her self-image. The therapist emphasized the irrationality and maladaptivity of her self-statements, and their development within her relationships within her family. In treatment, she gradually developed increasing feelings of self-confidence and assertion. Medication was terminated at the end of 6 months. By the end of the group and individual psychotherapy she had obtained employment within a department store and had been promoted to floor manager. She divorced her husband during treatment. She continued to suffer from feelings of anxiousness when dating, but the relationships were now more satisfying, meaningful, and promising.

**Dependent Personality Disorder**

DPD was, technically speaking, a new addition to DSM-III (American Psychiatric Association 1980) in that it had not been included within DSM-II (American Psychiatric Association 1968). However, a diagnosis of passive-dependent personality trait disturbance was included within the 1952 first edition of the American Psychiatric Association's diagnostic manual as a subtype to a passive-aggressive personality disorder, “characterized by helplessness, indecisiveness, and a tendency to cling to others as a dependent child to a supporting parent” (American Psychiatric Association 1952, p 37).

**Definition**

DPD involves a pervasive and excessive need to be taken care of that leads to submissiveness, clinging, and fears of separation (American Psychiatric Association 2000, Bornstein 2005, Pincus 2002). Persons with DPD will also have low self-esteem, and will often be self-critical and self-denigrating. Its primary diagnostic criteria include extreme difficulty making decisions without others’ input, need for others to assume responsibility for most aspects of daily life, extreme difficulty disagreeing with others, inability to initiate projects due to lack of self-confidence, and going to excessive lengths to obtain the approval of others (see DSM-IV-TR Criteria 301.6).

**Dependent Personality Disorder**

A. A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
2. needs others to assume responsibility for most major areas of his or her life
3. has difficulty expressing disagreement with others because of fear of loss of support or approval (Note: do not include realistic fears of retribution)
4. has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than to a lack of motivation or energy)
5. goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant
6. feels uncomfortable or helpless when alone, because of exaggerated fears of being unable to care for himself or herself
7. urgently seeks another relationship as a source of care and support when a close relationship ends
8. is unrealistically preoccupied with fears of being left to take care of himself or herself

Differential Diagnosis

Excessive dependency will often be seen in persons who have developed debilitating mental and general medical disorders, such as agoraphobia, schizophrenia, mental retardation, severe injuries, and dementia. However, a diagnosis of DPD requires the presence of the dependent traits since late childhood or adolescence (American Psychiatric Association 2000). One can diagnose the presence of a personality disorder at any age during a person’s lifetime, but if, for example, a DPD diagnosis is given to a person at the age of 75, this presumes that the dependent behavior was evident since the age of approximately 18 (i.e., predates the onset of a comorbid mental or physical disorder).

Deference, politeness, and passivity will also vary substantially across cultural groups. It is important not to confuse differences in personality that are due to different cultural norms with the presence of a personality disorder (Millon and Grossman 2005). The diagnosis of DPD requires that the dependent behavior be maladaptive, resulting in clinically significant functional impairment or distress.

Many persons with DPD will also meet the criteria for HPD and BPD (see Table 82–2). Persons with both DPD and HPD may display strong needs for reassurance, attention, and approval. However, persons with DPD tend to be more self-effacing, docile, and altruistic, whereas persons with HPD tend to be more flamboyant, assertive, and self-centered, and persons with BPD will tend to be much more dysfunctional and emotionally dysregulated (Bornstein 2005, Widiger et al. 1995).

Epidemiology and Comorbidity

DPD is among the most prevalent of the personality disorders (American Psychiatric Association 2000), occurring in 5–30% of patients and 2–4% of the general community (Mattia and Zimmerman 2001). A controversial issue is its differential sex prevalence (Bornstein 1995, Widiger 1998). DPD is diagnosed more frequently in females but there is some concern that there might be a failure to adequately recognize the extent of dependent personality traits within males (Bornstein 1995, Corbitt and Widiger 1995). Many studies have indicated that dependent personality traits provide a vulnerability to the development of depression in response to interpersonal loss (Blatt 2004, Bornstein 2005, Zuroff et al. 2004).

Course

Persons with DPD are likely to have been excessively submissive as children and adolescents, and some may have had a chronic physical illness or a separation anxiety disorder during childhood (American Psychiatric Association 2000), but there is actually little systematic research on the etiology of excessive dependency. To the extent that independent responsibility and initiative are required, job functioning will be impaired or unsatisfactory. Individuals with DPD are prone to mood disorders throughout life, particularly major depression and dysthymia, and to anxiety disorders, particularly agoraphobia, social phobia, and panic disorder (Bornstein 2005). However, the severity of the symptomatology may tend to lessen with age, particularly if the person has obtained a reliable, empathic partner.

The self-esteem of a person with DPD is said to depend substantially on the maintenance of a supportive and nurturant relationship (Blatt 2004, Bornstein 2005), and yet these intense needs for reassurance can have the paradoxical effect of driving the needed person away. The dependent person’s worst fears are then realized (i.e., he or she is abandoned and alone), and his or her sense of self-worth, -meaning, or -value is then furthered injured, perhaps even crushed by the rejection (Shahar et al. 2004). The dependent person might then indiscriminately select a readily available but unreliable, undependable, and perhaps even abusive person simply to be with someone. This partner would reaffirm the worst fears through the abuse, derogation, and denigration (i.e., conveying to the dependent person that he or she is indeed undesirable and unlovable, and that the relationship is again tenuous). In other words, a combination of evocative, reactive, and then proactive transactions with the environment are the means by which a dependent personality style can lead to depression.

Research on the relationship of dependency to depression, however, is not without fundamental concerns (Coyne et al. 2004). An important focus of future research will be a further articulation of the precise process or mechanism through which this association occurs. In theory, dependent personality traits contribute to the instability of intimate and supportive relationships through the expression of excessive needs for reassurance and/or pathogenic cognitions that contribute to intense feelings of helplessness and neediness. However, it is also possible that the emotional instability and pathologic attitudes are themselves the result of unstable interpersonal relationships. Dependency is a personality disposition that is seen much more often in women than in men (Bornstein 1996). A provocative reformulation of dependency in women is that the apparent feelings of insecurity may say less about the women than the persons with whom the women are involved. “Men and women may differ in what they seek from relationships, but they may also differ in what they provide to each other” (Coyne and Whiffen 1995, p 368). In other words, “Women might appear (and be) less dependent if they weren’t involved with such undependable men” (Widiger and Anderson 2003, p 63).

Etiology and Pathophysiology

There is very little systematic research on the etiology of dependency. Central to its etiology and pathophysiology is considered to be an insecure interpersonal attachment (Bornstein 2005, Paris 1998, Pincus 2002, Stone 1993). Insecure attachment and helplessness may be generated through a parent–child relationship, perhaps by a clinging parent or a continued infantilization during a time in which individuation and separation normally occurs (Gabbard 2000a, Thompson and Zuroff 1998). However, DPD may also represent an interaction of an anxious-inhibited temperament with inconsistent or overprotective parenting (Bornstein 2005, Rothbart et al. 2000). Dependent persons may turn to a parental figure to provide a reassurance, security, and confidence that they are unable to generate for themselves. They may eventually believe that their self-worth is contingent upon the worth or importance they have to another person (Beck et al. 1990).

Treatment

There are no empirically validated treatments for DPD. Treatment recommendations are essentially based on anecdotal...
that one boyfriend broke up with her explicitly because he experienced her as being too “needy” and “clingy.” She admitted that this was “not far from the truth” but had pleaded to him that she would no longer be so needy if only he would not leave her.

LC described her relationship with parents, particularly her mother, as being very close, supportive, and dependable. LC’s childhood history, however, included many examples of failures to develop an independent self-confidence. For example, she felt unable to attend a summer camp attended by her best friends because of fears of separation from her parents; she did attend the following summer but taxed the patience of the camp counselors with her demands for attention and support. Her parents verbally encouraged her to develop greater independence and self-confidence but they also would repeatedly give in to her requests for protection and support. LC’s mother in fact often appeared to be somewhat reluctant to let LC separate from her.

LC was seen in twice-weekly individual psychotherapy. Pharmacotherapy was provided for her anxious and depressive symptoms but was discontinued after 2 months due to complaints of side effects. Cognitive therapy focused on her self-denigrating beliefs of helplessness, behavioral therapy included a gradual shaping of independence from her parents, and insight therapy explored the relationship of her self-image with her relationships with her parents. Treatment was successful in developing sufficient independence and self-esteem for LC to feel comfortable and confident enough to return the following year to college. She successfully completed college although abandoned aspirations to pursue a social work career after she became married and had children of her own.

### Obsessive–Compulsive Personality Disorder

Obsessive–compulsive personality disorder (OCPD) has been included in every edition of the American Psychiatric Association’s diagnostic manual, although there appears to have been “ruminative doubts” about its name, shifting from compulsive personality in DSM-I (American Psychiatric Association 1952), to obsessive–compulsive personality in DSM-II (American Psychiatric Association 1968), back to compulsive personality in DSM-III (American Psychiatric Association 1980), and back again to obsessive–compulsive in DSM-III-R (American Psychiatric Association 1987).

#### Definition

OCPD includes a preoccupation with orderliness, perfectionism, and mental and interpersonal control (American Psychiatric Association 2000). OCPD is indicated by the presence of four or more of the eight diagnostic criteria presented in DSM-IV-TR Criteria 301.4.

#### Differential Diagnosis

Devotion to work and productivity will vary substantially across cultural groups. One should be careful not to confuse normal cultural variation in conscientiousness with the presence of this personality disorder (Millon and Grossman 2005). A diagnosis of OCPD requires that the
OCPD may at times resemble NPD, as both disorders can involve assertiveness, domination, achievement, and a professed perfectionism. However, the emphasis in OCPD will be on work for its own sake, whereas narcissistic persons will work to achieve only status and recognition (Widiger et al. 1995). Persons with OCPD will also be troubled by doubts, worries, and self-criticism, whereas the narcissistic person will tend to be overly self-assured.

Epidemiology and Comorbidity
Only 1–2% of the general community may meet the diagnostic criteria for the disorder (see Table 82–1) but this could be an underestimation (Costa et al. 2005). Up to 10% of the population has been estimated to be maladaptively stubborn, 4% excessively devoted to work, and 8% excessively perfectionistic (Nestadt et al. 1991). OCPD is one of the less frequently diagnosed personality disorders within inpatient settings, occurring in approximately 3–10% of patients (American Psychiatric Association 2000), but its prevalence may be much higher within private practice settings. This disorder does appear to occur more often in males than in females but exceptions to this finding have been reported (Corbitt and Widiger 1995).

Course
There is little systematic research on the childhood antecedents or adult course of OCPD. As children, some persons with OCPD may have appeared to be relatively well behaved, responsible, and conscientious. However, they may have also been overly serious, rigid, and constrained (Rothbart et al. 2000). As adults, it is expected that many will obtain good to excellent success within a job or career. They can be excellent workers to the point of excess, sacrificing their social and leisure activities, marriage, and family for their job (Stone 1993). Relationships with spouse and children are likely to be strained due to their tendency to be detached and uninvolved, and yet authoritarian and domineering with respect to decisions. A spouse may complain of a lack of affection, tenderness, and warmth. Relationships with colleagues at work may be equally strained by the excessive perfectionism, domination, indecision, worrying, and anger. Jobs that require flexibility, openness, creativity, or diplomacy may be particularly difficult. Persons with OCPD may be prone to various anxiety and physical disorders that are secondary to their worrying, indecision, and stress. Those with concomitant traits of angry hostility and competitiveness may be prone to cardiovascular disorders. Mood disorders may not develop until the person recognizes the sacrifices that have been made by his or her devotion to work and productivity, which may at times not occur until middle age. However, most will experience early employment or career difficulties or even failures that may result in depression.

Etiology and Pathophysiology
A variety of studies have indicated heritability for the trait of obsessionalness (Nigg and Goldsmith 1994). OCPD relates closely to the general personality domain of conscientiousness or constraint (Costa et al. 2005, Widiger et al. 2002), which itself develops via a childhood temperament of attentional self-regulation (Caspi et al. 2005). This domain of general personality structure includes facets
of deliberation (ruminating), self-discipline, achievement striving (workaholism), dutifulness (overconscientiousness and scrupulousness about matters of ethics and morality), order (preoccupation with details), and competence (perfectionism). There is considerable empirical support for the heritability of conscientiousness (Bouchard and Loehlin 2001).

Early psychoanalytic theories regarding OCPD concerned issues of unconscious guilt or shame (Gunderson and Gabbard 2000). A variety of underlying conflicts have since been proposed, including a need to maintain an illusion of infallibility to defend against feelings of insecurity, an identification with authoritarian parents, or an excessive, rigid control of feelings and impulses (Gabbard 2000a, Stone 1993). Any one or more of these conflicts might be relevant for a particular person with OCPD but there is quite limited empirical support for these particular models of etiology and pathology. OCPD includes personality traits that are highly valued within most cultures (e.g., conscientiousness) and some instances of OCPD may reflect exaggerated or excessive responses to the expectations of or pressures by parental figures.

Treatment
Persons with OCPD may fail to seek treatment for the OCPD symptomatology. They may seek treatment instead for disorders and problems that are secondary to their OCPD traits, including anxiety disorders, health problems (e.g., cardiovascular disorders), and problems within various relationships (e.g., marital, familial, and occupational). Treatment will be complicated by their inability to appreciate the contribution of their personality to these problems and disorders (Gunderson and Gabbard 2000, Stone 1993). It is not unusual for persons with OCPD to perceive themselves as being simply conscientious, dutiful, moral, and responsible, rather than perfectionistic, stubborn, rigid, domineering, and unavailable. Their lack of insight is complicated further by the contribution of their traits to various achievements and successes (e.g., career advancement) and to the control of negative affect (e.g., ability to control feelings of dysphoria during a crisis). The OCPD traits are not invariably or always maladaptive, and persons with this disorder may not appreciate the disorder's cost to their physical health, psychological well-being, and personal relationships.

Cognitive–behavioral techniques that address the irrationality of excessive conscientiousness, moralism, perfectionism, devotion to work, and stubbornness can be effective in the treatment of OCPD (Beck et al. 1990, Young and Klosko 2005). Persons with OCPD may in fact appreciate the rational approach to treatment provided by cognitive–behavioral therapy. A common difficulty though is the tendency to drift into lengthy and unproductive ruminations and intellectualized speculations (Beck et al 1990, Gunderson and Gabbard 2000, Stone 1993). Therapeutic techniques that emphasize the acknowledgment, recognition, and acceptance of feelings will therefore be useful (Gabbard 2000a). Gestalt techniques that focus upon and confront feeling states will often feel threatening to persons with OCPD but precisely for this reason they can also be quite revealing and useful. Persons with OCPD will attempt to control therapeutic sessions, and techniques that encourage uncontrolled, freely expressed associations to explore historical motivations for control, perfectionism, and workaholism are often helpful.

Persons with OCPD can be problematic in groups (Piper and Ogrodniczuk 2005). They will tend to be domineering, constricted, and judgmental. There is no accepted pharmacologic treatment for OCPD (Markovitz 2001, Soloff 2005). Some persons with OCPD will benefit from anxiolytic or antidepressant medications, but this will typically reflect the presence of associated features or comorbid disorders. The core traits of OCPD might not be affected by pharmacologic interventions.

Personality Disorder, Not Otherwise Specified
As indicated earlier, DSM-IV-TR includes a diagnostic category, PDNOS, for persons with a personality disorder who do not meet the diagnostic criteria for any one of the ten officially recognized diagnoses. PDNOS is one of the more commonly used personality disorder diagnoses in clinical practice (Verheul and Widiger 2004). It would not, of course, be possible to discuss the etiology, pathology, course, or treatment of the PDNOS disorder, as the diagnosis refers to a wide variety of personality types. However, one usage of PDNOS is for the two personality disorders presented in the appendix to DSM-IV-TR for criterion sets provided for further study, the passive-aggressive and the depressive (American Psychiatric Association 2000).

Passive–Aggressive (Negativistic) Personality Disorder
PAPD had been included in all prior editions of the American Psychiatric Association's diagnostic manual. It was in fact the single most frequently used personality disorder diagnosis during the Second World War (Malinow 1981). However, its status has been controversial for quite some time. It was included within DSM-III (American Psychiatric Association 1980) only under the provision that it not be diagnosed if the patient met the criteria for any other personality disorder (Frances 1980, Gunderson 1983). A primary concern has been whether it is a situational reaction to authoritative control or in fact a temporally stable personality trait. There have been no longitudinal studies to address this concern. It was shifted to the appendix of DSM-IV-TR because there had been little research to support its validity (Widiger et al. 1995). Objections have been raised in response to the decision to downgrade the diagnosis (Wetzler and Morey 1999) and its broadened criterion set may eventually prove to have more validity and clinical utility than the DSM-III-R version (McCann 1988, Milon 1993) but, as yet, there have been only a few scattered studies (e.g., Bradley et al. 2006, Joiner and Rudd 2002), none of which appears to address the primary concerns regarding its validity.

Definition
PAPD is a pervasive pattern of negativistic attitudes and passive resistance to authority, demands, responsibilities, or obligations (American Psychiatric Association 2000). PAPD can be diagnosed by the presence of four or more of the seven criteria presented in DSM-IV-TR Criteria: Passive–Aggressive Personality Disorder.
Passive–Aggressive Personality Disorder

A. A pervasive pattern of negativistic attitudes and passive resistance to demands for adequate performance, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Passively resists fulfilling routine social and occupational tasks
2. Complains of being misunderstood and unappreciated by others
3. Is sullen and argumentative
4. Unreasonably criticizes and scorns authority
5. Expresses envy and resentment toward those apparently more fortunate
6. Voices exaggerated and persistent complaints of personal misfortune
7. Alternates between hostile defiance and contrition

B. Does not occur exclusively during major depressive episodes and is not better accounted for by dysthymic disorder.

Differential Diagnosis

It is particularly important when assessing for PAPD to recognize that passive–aggressive behavior might be confined to settings in which persons have lost a freedom, responsibility, or decision-making authority that was previously available to them and overt expressions of assertiveness or opposition are being discouraged. For example, it would not be surprising to observe passive–aggressive behavior within the military, prison, or some inpatient hospitals. It is important in such settings to verify that the negativistic behavior was evident earlier and is currently evident within other situations.

Epidemiology and Comorbidity

Approximately 1–2% of the community will meet the DSM-III-R criteria for PAPD (see Table 82–1). Up to 5% of patients were being diagnosed with PAPD (McCann 1988, Milon 1993, Wetzler and Morey 1999). The rate was higher when semistructured interviews were used but still low compared to most other personality disorders. The prevalence rate with the DSM-IV-TR criteria is likely to be higher, given the expansion of the disorder from simply a passive resistance to demands for adequate performance to a more general negativism (Millon 1993). An approximately equal prevalence of males and females has traits that meet the criteria for the disorder based upon the DSM-III and DSM-III-R criteria (Corbitt and Widiger 1995). However, the broader formulation of negativism resembles closely the general trait of oppositionalism, characterized by the tendency to be complaining, discontented, grumbling, whining, and argumentative, which does appear to occur more often in males than in females (Costa et al. 2001).

Course

Many persons with PAPD may have met the criteria for an oppositional defiant disorder during childhood, which is also characterized by the tendency to be irritable, complaining, oppositional, argumentative, and negativistic. In DSM-III, PAPD was said to be the adult variant of oppositional defiant disorder, comparable to the relationship of ASPD to conduct disorder (American Psychiatric Association 1980). As adults, impairment is likely to be particularly evident with respect to employment. Persons with PAPD would be irresponsible, lax, and negligent employees, as well as resistant, oppositional, and even hostile. Resolution of interpersonal conflicts will be difficult, due to the tendency of the passive–aggressive person to blame others. They will be argumentative, sullen, and critical of their peers and friends, who may not tolerate their antagonism.

Etiology and Pathophysiology

Central to the psychopathology of PAPD is considered to be bitter resentment (Millon et al. 1996). Passive–aggressive persons are said to have a hostile, angry, and bitter attitude toward the world. There are no data on its heritability or psychosocial etiology. However, the DSM-IV-TR diagnosis of PAPD appears to involve the general personality traits of oppositionalism, irresponsibility, and laxness (see Table 82–3), for which there is considerable empirical support for heritability (Widiger and Trull 2007). It has been suggested that passive–aggressive behavior is due in part to conflicts concerning dependency and resentment, or a history of mistreatment and neglect (McCann 1988). One might find a history of being exploited, neglected, mistreated, or abused by persons upon whom the person with PAPD relied. Negativistic traits may also be modeled by parental figures.

Treatment

Persons with PAPD would rarely enter treatment to make effective changes to their personality or behavior. They are more likely to seek treatment for Axis I disorders (e.g., depression, anxiety, or somatoform disorder), or for marital, family, or occupational problems. The initiation of treatment is often at the insistence of a spouse, relative, or employer (Gabbard 2000a, Stone 1993). They can be very difficult patients to treat due to their tendency to be blaming, argumentative, pessimistic, and passively resistant (Milon et al. 1996). It is important for the therapist to remain supportive and empathic, carefully and benignly offering observations, suggestions, and reflections on their tendency to be their own worst enemy. Cognitive treatment can be useful to directly address the false perceptions, assumptions, and attributions (Beck et al. 1990) as long as the therapist is not drawn into unproductive disagreements and arguments. It is common for therapists to become frustrated, impatient, and defensive in response to the negativism, criticism, and complaints. Periodic consultation with colleagues is advisable. Group therapy is often helpful once the patient has developed a commitment to the group, as the various members can provide consistent and confirmatory feedback regarding the negativistic and passive–aggressive behavior. There is no known pharmacologic treatment for PAPD (Markovitz 2001, Soloff 2005).
Depressive Personality Disorder

Depressive personality disorder (DPPD) was proposed for inclusion in DSM-III (American Psychiatric Association 1980) and DSM-III-R (American Psychiatric Association 1987), but there were concerns that it may not be adequately distinguished from the mood disorder of dysthymia (Klein 1999, Phillips et al. 1995, 1998, Ryder and Bagby 1999, Widiger 1999). This is somewhat ironic, as much of the research literature that guided the development of early onset dysthymia concerned research on depressive personality traits (Keller 1989, Keller and Russell 1996). A field trial by the DSM-IV-TR Mood Disorders Work Group indicated that many persons do meet diagnostic criteria for DPPD rather than early onset dysthymia (Phillips et al. 1995, Widiger 1999). Many persons diagnosed with early onset dysthymia may not be adequately described as having a disorder that is confined to the regulation or control of their mood (Klein 1999, Phillips et al. 1998). However, it was decided that the DSM-IV-TR diagnostic criteria for DPPD lacked sufficient empirical support to warrant full recognition (Gunderson 1998).

Definition

DPPD is a pervasive pattern of depressive cognitions and behaviors that have been evident since adolescence and characteristic of everyday functioning (American Psychiatric Association 2000). These are persons who characteristically display a gloominess, cheerlessness, pessimism, brooding, rumination, and dejection. DPPD would be diagnosed by the presence of five or more of the seven criteria presented in DSM-IV-TR Criteria: Depressive Personality Disorder.

Differential Diagnosis

There may be no meaningful distinction between DPPD and early onset dysthymia, as suggested within DSM-IV-TR (American Psychiatric Association 2000). The DSM-IV-TR Personality Disorders Work Group developed a criterion set for DPPD that placed particular emphasis on cognitive features as a means of distinguishing DPPD from a more vegetative dysthymia (Widiger et al. 1995). This criterion set was able to distinguish DPPD from cases of dysthymia within the mood disorders field trial (Phillips et al. 1995) but the criterion set for dysthymia was subsequently modified to include these cognitive features. The alternative criteria for dysthymia were placed in the appendix to DSM-IV-TR along with the criterion set for DPPD (Phillips et al. 1995, Widiger 1999). Some may prefer to use the diagnosis of early onset dysthymia, but a dysregulation in mood may not adequately explain why some persons are characterized by chronic attitudes of pessimism, negativism, hopelessness, and dejection. Quite a bit of research continues to be conducted on the validity of depressive personality and its distinction from dysthymia (e.g., Huprich et al. 2005, Pettit and Joiner 2006, Ryder et al. 2006a, 2006b).

Epidemiology and Comorbidity

There are only limited data on the prevalence of DPPD within the general population. DPPD is likely to be comorbid with early onset dysthymia, although not all cases of DPPD will meet the DSM-IV-TR criteria for dysthymia (Klein 1999, Phillips et al. 1995). Many of the persons who meet the criteria for DPPD will also likely meet the DSM-IV-TR criteria for PAPD and BPD.

Course

There is considerable research on the childhood antecedents (Caspi et al. 2005) and lifetime course (Roberts and DelVecchio 2000) of depressive personality traits. As children, persons with DPPD will have been pessimistic, gloomy, passive, and withdrawn. Performance in school is often inadequate to poor. This behavior pattern continues essentially unchanged into and through adulthood. Some, however, may eventually become good workers, exhibiting tremendous discipline and devotion to their work (Phillips et al. 1995). Relationships with peers and sexual partners, however, are invariably problematic. They will be gloomy and irritable company, and will have difficulty finding pleasure, joy, or satisfaction in leisure activities (Millon et al. 1996). They may also be quite withdrawn and lonely, but lack an apparent motivation or energy to seek or maintain relationships.

Etiology and Pathophysiology

Trait depression is a facet of the personality domain of neuroticism or negative affectivity, which has a well-documented heritability within the general population (Bouchard and Loehlin 2001, Jang et al. 1998, Jang and Vernon 2001). There are also data to indicate a shared genetic variance with mood disorder, consistent with the hypothesis that DPPD may involve a depressive temperament that pervades general personality functioning as well as providing a disposition toward mood disorders (Klein 1999). A characteristically low self-esteem, self-criticism, pessimism, brooding, and guilt could also result from continued, sustained criticism, derogation, and discouragement by a significant parental

---

figure that is accepted and incorporated by the child (Stone 1993).

Treatmen
Many persons with DPPD will be referred or seek treatment for a depressive mood disorder. It is important in such cases to recognize the extent to which the depressed mood reflects their fundamental view of themselves and the world. Their pessimism involves more than simply a dysregulation of mood. Cognitive–behavioral techniques have demonstrated efficacy in the treatment of depressive personality traits (Beck et al. 1990). The depressive individual's pessimistic view of themselves and their future should be systematically challenged. Explorations of the faulty reasoning, arbitrary inferences, selective perceptions, and misattributions can be influential in overcoming the pessimistic, gloomy, critical, and negativistic attitudes. Audio- or videotaped role-playing is useful in helping the person recognize the occurrence and pervasiveness of the depressive cognitions, and in generating, developing, and rehearsing more realistic and accurate reasoning. However, exploration of the source for and historical development of self-defeating behaviors may also be helpful, not only to undermine their credibility and validity within current relationships and situations but also to address any motivation for their perpetuation (Stone 1993).

Persons with DPPD will also be responsive to antidepressant pharmacotherapy, particularly tricyclic antidepressants (Klein 1999, Markovitz 2001, Widiger 1999).

Acknowledgments
The authors express their appreciation to Cynthia Sanderson for her help in the development of an earlier version of this chapter. Definition
This diagnostic category recognizes the variety of ways in which specific psychological or behavioral factors can adversely affect medical illnesses. Such factors may contribute to the initiation or the exacerbation of the illness, interfere with treatment and rehabilitation, or contribute to morbidity and mortality. Psychological factors may themselves constitute risks for medical diseases, or they may magnify the effects of nonpsychological risk factors. The effects may be mediated directly at a pathophysiological level (e.g., psychological stress inducing myocardial ischemia) or through the patient’s behavior (e.g., noncompliance).

The criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition, Revised (DSM-III-R) for this diagnosis were brief and emphasized the temporal relationship of psychological factors to the initiation or exacerbation of the medical condition. The criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) were expanded in two ways. The overall category was expanded to include situations in which psychological factors interfered with medical treatment, posed health risks, or caused stress-related pathophysiological changes. This diagnosis was also structured in DSM-IV-TR so that both the psychological factor and the general medical condition are to be specified. The psychological factor can be an Axis I or Axis II mental disorder (e.g., major depressive disorder aggravating coronary artery disease (CAD)), a psychological symptom (e.g., anxiety exacerbating asthma), a personality trait or coping style (e.g., type A behavior contributing to the development of CAD), maladaptive health behaviors (e.g., unsafe sex in a person with human immunodeficiency virus (HIV) infection), a stress-related physiological response (e.g., tension headache), or other or unspecified psychological factors. The medical condition is also noted on Axis III. The expansion and elaboration of diagnostic criteria in DSM-IV-TR were based on an extensive review of the literature by a DSM-IV-TR work group organized by organ system and medical specialty categories. Their work has been published and is a source of more detail for the interested reader. (Stoudemire 1995).

Psychological Factors Affecting Medical Condition

James L. Levenson
Department of Psychiatry, Virginia Commonwealth University School of Medicine, Richmond, VA, USA

Psychological Factors Affecting Physical Condition

A. Psychologically meaningful environmental stimuli are temporally related to the initiation or exacerbation of a specific physical condition or disorder (recorded on Axis III).

B. The physical condition involves either demonstrable organic pathology (e.g., rheumatoid arthritis) or a known pathophysiological process (e.g., migraine headache).

C. The condition does not meet the criteria for a somatoform disorder.

The subject of psychological factors affecting medical condition (PFAMC) has become the focus of intense research because of the illumination it may provide of basic disease mechanisms (e.g., psychoneuroimmunology) and because of the intense interest in improving both the outcomes and the efficiency of health care delivery. In epidemiological studies, several psychiatric disorders increase the likelihood of mortality (Bruce et al. 1994), especially depression, bipolar disorder, schizophrenia, and alcohol abuse or dependence. Psychiatric disorders may negatively affect outcome
in medical illness, increasing adverse events, length of stay in general hospital patients, and health care costs (Saravay 2006, Walker et al. 2003, Daumit et al. 2006, Deykin et al. 2001). Interest has been further increased by intervention trials aimed at psychological factors or disorders that have demonstrated improvements in medical outcomes and in quality of life in patients with serious medical disorders.

It should be evident that this diagnosis is not really a discrete diagnostic category but rather a label for the interactive effects of psyche on soma. Mind–body interactions have long been a focus of interest, both in health and in disease. Psychiatric illness and medical disease frequently coexist. Psychiatrists and investigators of past eras were misled by this frequent comorbidity into premature conclusions that the psychological factors were preeminent in the causation of the medical disorders, and these were designated psychosomatic. A more modern approach has been to recognize that all medical illnesses are potentially affected by many different factors in the biological, psychological, and social realms. The earlier designation of certain disorders as psychosomatic (e.g., peptic ulcer disease) overvalued the contribution of psychological factors to those disorders and undervalued their contribution to other medical disorders (e.g., cancer). Furthermore, whereas labeling medical illnesses as psychosomatic drew attention to the importance of mind–body interactions, it unfortunately and falsely implied to many patients and physicians that the illness was basically psychogenic, that the symptoms were not “real,” and that the illness was somehow the patient’s fault.

The diagnosis of PFAMC focuses attention on one causal direction in the interactions between psyche and soma, that is, the effects of psychological factors on the medical condition (Figure 83–1). This represents a heuristic simplification, highlighting a particular process for further exploration, understanding, and intervention. In most patients, there are effects in the other direction as well (i.e., the effects of general medical illness on psychological function). Furthermore, both mind and body interact with social and environmental factors both dramatic (e.g., poverty, racism, war) and more subtle (e.g., employment status, neighborhood) (Roux et al. 2001), that affect the incidence and outcome of medical illness. Diagnosing PFAMC may help psychiatrist and patient address an important dimension of care, but the other “arrows” of Figure 83–1 often warrant attention too.

**Assessment and Diagnosis**

The diagnosis of PFAMC differs from most other psychiatric diagnoses in its focus on the interaction between the mental and medical realms. As noted, the criteria require more than
that the patient has both a medical illness and contemporaneous psychological factors, because their coexistence does not always include significant interactions between them. To make the diagnosis of PFAMC, either the factors must have influenced the course of the medical condition, interfered with its treatment, contributed to health risks, or physiologically aggravated the medical condition.

Let us consider each of these four ways of making the diagnosis of PFAMC in more detail. The psychological factor’s influence on the course of a general medical condition can be inferred from a close temporal relationship between the factor and the development or exacerbation of the medical condition (or delayed recovery). For example, a 45-year-old male executive reports symptoms sounding like typical angina, but occurring only on weekends. Further questioning reveals that he is depressed over the deterioration of his marriage. During the week, he works late and has limited contact with his family, but he spends the weekend at home. The symptoms began after he and his wife started arguing every weekend. The temporal link between onset and recurrence of angina and marital arguments supports a diagnosis of PFAMC.

PFAMC can also be diagnosed when the psychological factor interferes with treatment, including not seeking medical care, not following up, nonadherence to prescribed drugs or other treatment, or maladaptive modifications in treatment made by the patient or family. The same 45-year-old executive with angina rejected his physician’s recommendations for further assessment and treatment. He said, “I do get upset at home but I feel just fine at the office, so there couldn’t be anything really wrong with me.” The patient is able to acknowledge marital discord, but the defense of denial clouds his perception of his physical health and blocks appropriate medical care. This is another form of PFAMC.

PFAMC can also be diagnosed when the psychological factor contributes to health risks, exemplified by the same 45-year-old executive’s increasing his smoking and drinking despite his physician’s warnings. (“It’s the only way I can cope with my wife.”) Finally, PFAMC is an appropriate diagnosis when there are stress-related physiological responses precipitating or exacerbating symptoms of the medical condition. The same man observes that angina is most likely to occur after marital arguments during which he becomes irate, yelling, slamming doors, and throwing things.

When a patient’s medical illness is faring worse than expected and not responding well to standard treatment, physicians should and often do consider whether a psychological factor may be responsible for the poorer than expected outcome. This is a far from trivial task. To ignore the possibility of PFAMC may miss the crucial barrier to the patient’s recovery. On the other hand, premature or facile attribution to psychological factors may lead the physician to overlook medical or social explanations for “treatment-resistant disease” and unfairly blame the patient, with resultant further deterioration in health outcomes and the physician–patient relationship.

To illustrate, a common clinical problem is the brittle diabetic adolescent with labile blood glucose levels and frequent episodes of ketoacidosis and hypoglycemia, despite vigorous attempts by the physician to improve diabetic management and glucose control. The considerable difficulty

in controlling such patients’ diabetes is often attributed to adolescents’ dislike of lifestyle restrictions, their tendency to act out and rebel against authority figures, their denial of vulnerability, their ambivalence about their need for nurturance, and their wish to be “normal”. There are many adolescent (and some adult) diabetic patients for whom these psychological issues do play an important role in undermining diabetes management through noncompliance regarding medication, diet, visits to the physician, substance use, and activity limitations. However, psychological factors do not always account for brittleness and are sometimes incorrectly suspected. It has been demonstrated that much of the difficulty in achieving stable glucose control in adolescent diabetics is the result of the dramatically labile patterns of hormone secretion (cortisol, growth hormone) typical of adolescence, independent of psychological status.

PFAMC has descriptive names for subcategories described as follows.

### Mental Disorder Affecting a General Medical Condition

If the patient has a mental disorder meeting criteria for an Axis I or Axis II diagnosis, the diagnostic name is mental disorder affecting medical condition, with the particular medical condition specified. In addition to coding PFAMC, the specific mental disorder is also coded on Axis I or Axis II. Examples include major depressive disorder that reduces energy and compliance in a hemodialysis patient; panic disorder that makes an asthmatic patient hypersensitive to dyspnea; and schizophrenia in a patient with recurrent ventricular tachycardia who refuses placement of an automatic implantable defibrillator because he fears it will control his mind.

### Psychological Symptoms Affecting a General Medical Condition

Patients who have psychological symptoms that do not meet the threshold for an Axis I diagnosis may still experience important effects on their medical illness, and the diagnosis would be psychological symptoms affecting a medical condition. Examples include anxiety that aggravates irritable bowel syndrome (IBS); depressed mood that hinders recovery from hip replacement surgery; and anger that interferes with rehabilitation after spinal cord injury.

### Personality Traits or Coping Style Affecting a General Medical Condition

This may include personality traits or coping styles that do not meet criteria for an Axis II disorder and other patterns of response considered to be maladaptive because they may pose a risk for particular medical illnesses. An example is the competitive hostility component of the type A behavior pattern, and its impact on CAD. Maladaptive personality traits or coping styles are particularly likely to interfere with the physician–patient relationship as well as the patient’s relationships with other caregivers.

### Maladaptive Health Behaviors Affecting a General Medical Condition

Many maladaptive health behaviors have significant effects on the course and treatment of many medical conditions. Examples include sedentary lifestyle, smoking, abuse of
alcohol or other substances, and unsafe sexual practices. If the maladaptive behaviors can be better accounted for by an Axis I or Axis II disorder, the first subcategory (mental disorder affecting a medical condition) should be used instead.

Stress-Related Physiological Response Affecting a General Medical Condition
Examples of stress-related physiological responses affecting a medical condition include the precipitation by psychological stress of angina, cardiac arrhythmia, migraine, or attack of colitis in medically vulnerable individuals. In such cases, stress is not the cause of the illness or symptoms; the patient has an underlying medical condition (CAD, migraine, or ulcerative colitis), and the stressor instead represents a precipitating or aggravating factor.

Other or Unspecified Psychological Factors Affecting a General Medical Condition
There are other psychological phenomena that may not fit within one of these subcategories. An interpersonal example is marital dysfunction. A cultural example is the extreme discomfort a woman from some cultures may experience being alone with a male physician, even while she is fully dressed. A religious example is a Jehovah’s Witness who ambivalently refuses blood transfusion. These fall under the residual category of other or unspecified psychological factors affecting a medical condition.

Differential Diagnosis
As noted before, the close temporal association between psychiatric symptoms and a medical condition does not always reflect PFAMC. If the two are considered merely coincidental, then separate psychiatric and medical diagnoses should be made. In some cases of coincident psychiatric and medical illness, the mental symptoms are actually the result of the medical condition (i.e., the causality is in a direction opposite from that of PFAMC). When a medical condition is judged to be pathophysiologically causing the mental disorder (e.g., hypothyroidism causing depression), the correct diagnosis is the appropriate mental disorder due to a general medical condition (e.g., mood disorder due to hypothyroidism, with depressive features). In PFAMC, the psychological or behavioral factors are judged to precipitate or aggravate the medical condition.

Substance use disorders may adversely affect many medical conditions, and this can be described through PFAMC. However, in some patients, all of the psychiatric and medical symptoms are direct consequences of substance abuse, and it is usually parsimonious to use just the substance use disorder diagnosis. For example, a patient with delirium tremens after alcohol withdrawal would receive a diagnosis of alcohol withdrawal delirium, not PFAMC, but a patient with alcohol dependence who repeatedly missed hemodialysis treatments because of intoxication would receive diagnoses of alcohol dependence and PFAMC (mental disorder affecting end stage renal disease).

Patients with somatoform disorders (e.g., somatization disorder, hypochondriasis) present with physical complaints which may mimic a medical illness, but the somatic symptoms are actually accounted for by the psychiatric disorder. In principle, it might seem that somatoform disorders are easily distinguished from PFAMC, because PFAMC requires the presence of a diagnosable medical condition. The distinction in practice is sometimes difficult because the patient may have both a somatoform disorder and one or more medical disorders. For example, a patient with seizures regularly precipitated by emotional stress might have true epilepsy aggravated by stress (PFAMC), pseudoseizures (conversion disorder), or both.

Epidemiology and Comorbidity
Because this diagnosis describes a variety of possible interactions between the full range of psychiatric disorders (as well as symptoms and behaviors) on the one hand and the full range of medical diseases on the other, it is impossible to estimate overall rates of prevalence or incidence. We can start, however, by noting how frequently medical and psychiatric disorders coexist. Psychiatric problems are common in medical patients, although the measured frequency varies, depending on the criteria and method of measurement used. A reasonable estimate is that 25–30% of medical outpatients and 40–50% of general medical inpatients have diagnosable psychiatric disorders (Table 83–1). Most common in medical outpatients are depression, anxiety, and substance abuse; medical inpatients most often have cognitive impairment (delirium, dementia), depression, and substance abuse. Depression, both as a diagnosis and as a symptom has been better studied in the medically ill than any other psychiatric syndrome. Major depressive disorder occurs in 18–25% of patients with serious coronary disease, in 25% of those with cancer, and at three times the normal rate in diabetic patients. Individuals presenting with symptoms of chronic fatigue have a 50–75% lifetime prevalence of major depression (Sharpe and O’Malley 2005).

| Table 83–1 Prevalence of Selected Psychiatric Disorders |
|--------------------------|--------------------------|--------------------------|--------------------------|
| Disorder                 | Community                | Primary Care Patients    | Medical Inpatients       |
| All psychiatric disorders| 15–20%                   | 25–30%                   | 40–50%                   |
| Depression               |                          |                          |                          |
| Depressive symptoms      | 10–15%                   | 10–30%                   | 20–35%                   |
| Major depressive disorder| 2–4%                     | 5–10%                    | 5–25%                    |
| Anxiety                  |                          |                          |                          |
| Anxiety symptoms         | 10–20%                   | 12–20%                   | 20–30%                   |
| Panic disorder           | 1–2%                     | 2–15%                    | —                       |
| Cognitive disorders      | 1%                       | 5–10%                    | 15–20%                   |
| (>65 yr)                 |                          | (>65 yr)                 | 30–50%                   |

Nonpsychiatric physicians underdiagnose and undertreat psychiatric disorders in the medically ill. Medical disorders are also common in patients seen for mental health treatment, and mental health specialists often underrecognize the presence and significance of coexisting medical disorders. Regardless of whether the patient has come seeking
medical care or mental health care, medical and psychiatric problems are often both present. Such coincidence by itself is not sufficient for the diagnosis of PFAMC. In some cases, the illnesses may coexist with little effect on each other; in other cases, the effects of the medical illness on the psychiatric condition may be more important. The diagnosis of PFAMC in DSM-IV-TR is reserved for patients in whom psychological factors adversely affect a medical condition in a specifiable way.

Course
Given the wide range of psychiatric disorders and psychological factors that may affect medical illness and the large number of different medical disorders that may be influenced, there are no general rules about the course of the PFAMC interaction. Psychological factors may have minor or major effects at a particular point or throughout the course of a medical illness. We do know in general that patients with medical disorders who also have significant psychological symptoms have poorer outcomes and higher medical care costs than those patients with the same medical disorders but without psychological distress. A number of studies now document that psychological or psychiatric problems (particularly cognitive disorder, depression, and anxiety) in general medical inpatients are associated with significant increases in length of hospital stay (Saravay 2006). Psychosocial interventions have been able to improve outcomes in medical illness, sometimes with an attendant savings in health care costs (Saravay 2006).

The impact of psychological factors on the course and natural history of medical disorders is discussed further in this chapter in the context of specific diseases.

Etiology and Pathophysiology
How do psychological factors affect medical illnesses? Physicians have long recognized that psychological factors seem to affect medical illnesses, and research elucidating the intervening causal mechanisms is now rapidly growing. From their clinical experience, physicians recognize many ways in which psychological factors affect the onset, progression, and outcome of their patients’ illnesses. First, psychological factors may promote other known risks for medical illness. Smoking is a risk factor for heart disease, cancer, and pulmonary and many other diseases, and individuals with schizophrenia or depression are much more likely to smoke than the general population. A wide variety of psychiatric illnesses are associated with an increased likelihood of abuse of other substances. Depression and schizophrenia also are associated with a sedentary lifestyle. Patients with affective disorders often have chronic pain and chronically tend to overuse analgesics. Individuals with schizophrenia, bipolar disorder, and some personality disorders are more likely to engage in unsafe sex, which in turn increases the risk of sexually transmitted diseases, including HIV infection and hepatitis B. Depression, eating disorders, and other emotional and behavioral factors affect the pattern and content of diet.

In addition to promoting known risk factors for medical illness, psychological factors also have an impact on the course of illness by influencing how patients respond to their symptoms, including whether and how they seek care. For example, the defense mechanism of denial may lead an individual to ignore anginal chest pain, attribute it to indigestion, delay seeking medical attention, or minimize the pain when describing it to a physician. This tends to result in treatment delay after the acute onset of coronary symptoms, with consequently greater morbidity and mortality. Anxiety is also a common cause of avoidance or delay of health care; phobic fears of needles, sight of blood, surgery, and other health care phobias are common (Noyes et al. 2000). Patients may also neglect their symptoms and fail to promptly seek medical care because of depression, psychosis, or personality traits (e.g., procrastination).

Psychological factors also affect the course of illness through their effects on the physician–patient relationship, since they influence both patients’ health behaviors and physicians’ diagnostic and treatment decisions. A substantial proportion of the excess mortality experienced by individuals with mental disorders is explained by their receiving poorer quality medical care (Druss et al. 2001a). One explanation for the poorer quality and outcomes of medical care in patients with both serious medical and mental illnesses is the lack of integration between their medical and mental health care (Druss et al. 2001b). Psychological factors can also reduce a patient’s compliance with diagnostic recommendations, treatment, and lifestyle change, and can interfere with rehabilitation through impairment of motivation, understanding, optimism, or tolerance. A meta-analysis found that patients with depression are three times as likely to be noncompliant with medical treatment than patients without (D’Mattoo et al. 2000). In addition, many of the effects of psychological factors on medical illness appear to be mediated through a wide array of social factors, including social support, job strain, disadvantaged socioeconomic and educational status, and marital stress.

There is an increasing body of scientific evidence that psychological factors, in addition to their impact on classic (nonpsychological) risk factors, patient behaviors, and the physician–patient interaction, have direct effects on pathophysiological processes. For example, stress has been experimentally shown to cause myocardial ischemia in patients with coronary disease. Stress and depression are associated with a wide range of immunological effects (Graham et al. 2006, Schiepers et al. 2005). Many psychiatric disorders (especially mood disorders) are associated with disruptions in homeostasis, including sleep architecture, other circadian rhythms, and endocrine secretion and feedback. For example, depression causes increased bone remodeling and decreased bone density (Herran et al. 2000). That such effects occur is well established, but the magnitude of their clinical significance in medical disease is often unclear, and full explanatory causal linkages have for the most part not been demonstrated yet. Nevertheless, investigators have learned a great deal about changes in autonomic, hematologic, endocrine, immunologic, and sensory function, as well as gene expression that bring us closer to understanding how psychological factors may affect medical illness. These issues of pathophysiology are discussed later in this chapter for each organ system or specialty category.

Treatment
Management of psychological factors affecting the patient’s medical condition should be tailored both to the particular psychological factor of relevance and to the medical outcome of concern. Some general guidelines, however, can be...
helpful. The physician, whether in primary care or a specialty, should not ignore apparent psychiatric illness. Unfortunately, this occurs all too often because of discomfort, stigma, lack of training, or disinterest. Referring the patient to a mental health specialist for evaluation is certainly better than ignoring the psychological problem but should not be regarded as “disposing” of it, because the physician must still attend to its potential impact on the patient’s medical illness. Similarly, psychiatrists and other mental health practitioners should not ignore coincident medical disease and should not assume that referral to a nonpsychiatric physician absolves them of all responsibility for the patient’s medical problem.

Mental Disorder Affecting a Medical Condition
If the patient has a treatable Axis I disorder, treatment for it should be provided. Whereas this is obviously justified on the basis of providing relief from the Axis I disorder, psychiatric treatment is further supported by the myriad ways in which the psychiatric disorder may currently or in the future adversely affect the medical illness. The same psychopharmacological and psychotherapeutic treatments used for Axis I mental disorders are normally appropriate when an affected medical condition is also present. However, even well-established psychiatric treatments supported by randomized controlled trials have seldom been validated in the medically ill, who are typically excluded from the controlled trials. Thus, psychiatric treatments may not always be directly generalizable to, and often must be modified for, the medically ill.

When prescribing psychiatric medications for patients with significant medical comorbidity, the psychiatrist should keep in mind potential adverse effects on impaired organ systems (e.g., anticholinergic exacerbation of postoperative ileus; tricyclic antidepressant causing completion of heart block), changes in pharmacokinetics (absorption, protein binding, metabolism, and excretion), and drug–drug interactions. Psychotherapy may also require modification in patients with comorbid medical illness, including greater flexibility regarding the length and frequency of appointments, and deviations from standard therapeutic abstinence and neutrality (i.e., refraining from telling patients what to do and taking action on their behalf) (Perry and Viederman 1981).

Psychotherapists treating patients with PFAMC should usually be much more active in communicating with other health care professionals caring for the patient (with the patient’s consent) than is usually the case in psychotherapy.

If the patient has an Axis II personality disorder or other prominent personality or coping style, the psychiatrist should modify the patient’s treatment accordingly, which is usually more easily accomplished than trying to change the patient’s personality. For example, patients who tend to be paranoid or mistrustful should receive more careful explanations, particularly before invasive or anxiety-provoking procedures. With narcissistic patients, the psychiatrist should avoid relating in ways that may seem excessively paternalistic or authoritarian to the patient. With some dependent patients, it may be advisable to be more directive, without overdoing it and fostering excessive dependency.

Psychological Symptoms Affecting a General Medical Condition
In some instances, psychiatric symptoms not meeting the threshold for an Axis I diagnosis will respond positively to the same treatments used for the analogous Axis I psychiatric disorder, with appropriate modifications as noted before. There is not a great amount of treatment research on subsyndromal psychiatric symptoms, and even less in patients with comorbid medical illness, so this area of practice remains less evidence-based. Some psychiatric symptoms affecting a medical condition may be amenable to stress management and other behavioral techniques as well as appropriate reassurance.

Any intervention directed by the psychiatrist at a particular patient’s psychological symptoms or behavior should be grounded in exploratory discussion with the patient. Interventions without such grounding tend to seem at best superficial and artificial and at worst are entirely off the mark. For example, if the psychiatrist wrongly presumes to know why a particular patient seems anxious without asking, the patient is likely to feel misunderstood. Facile, nonspecific reassurance can undermine the physician–patient relationship, because the patient is likely to feel that the psychiatrist is out of touch with and not really interested in the patient’s experience. It is especially important with depressed patients that psychiatrists avoid premature or unrealistic reassurance or an overly cheerful attitude; this tends to alienate depressed patients, who feel that their psychiatrist is insensitive and either does not understand or does not want to hear about their sadness. Physicians should provide specific and realistic reassurance, emphasizing a constructive treatment plan, and mobilize the patient’s support system.

Personality Traits or Coping Style Affecting a General Medical Condition
As with Axis II disorders affecting a medical condition, psychiatrists should be aware of the personality style’s effects on the physician–patient relationship and modify management to better fit the patient. For example, with type A “time urgent” patients, psychiatrists may need to be more sensitive to issues of appointment scheduling and waiting times. Group therapy interventions can enhance active coping with serious medical illnesses like cancer, heart disease, and renal failure but to date have usually been designed to be broadly generalizable rather than targeted to one particular trait or style (with the exception of type A behavior).

Another general guideline is not to attack or interfere with a patient’s defensive style unless the defense is having an adverse impact on the medical illness or its management. Psychiatrists are particularly tempted to intervene when the defense is dramatic, breaks with reality, or makes the psychiatrist uncomfortable.

For example, denial is a defense mechanism that reduces anxiety and conflict by blocking conscious awareness of thoughts, feelings, or facts that an individual cannot face. Denial is common in the medically ill but varies in its timing, strength, and adaptive value. Some patients are aware of what is wrong with them but consciously suppress this knowledge by avoiding thinking about or discussing it. Others cope with the threat of being overwhelmed by their illness by unconsciously repressing it and thereby remain unaware of their illness. Marked denial, in which the patient emphatically refuses to accept the existence or significance of obvious symptoms and signs of the disease, may be seen by the psychiatrist as an indication that the patient is “crazy” because the patient seems impervious to rational
impulse to flight. A better strategy for the psychiatrist is to
the patient into cooperation will intensify denial and the
ological flaws, including use of small biased samples, limited
inclusion of all valuable studies and all medical disorders.
vidence from controlled studies. Space considerations preclude
factors on selected medical disorders are reviewed. The pri-
section, but rather encourage hope and optimism. When denial
is extreme, patients may refuse vital treatment or threaten
to leave against medical advice. Here, the psychiatrist must
try to help reduce denial but not by directly assaulting the
patient’s defenses. Because such desperate denial of reality
usually reflects intense underlying anxiety, trying to scare the
patient into cooperation will intensify denial and the
impulse to flight. A better strategy for the psychiatrist is to
avoid directly challenging the patient’s claims while simulta-
ously reinforcing concern for the patient and maximizing the
patient’s sense of control.

Maladaptive Health Behavior Affecting a General
Medical Condition
This is an area of research with many promising approaches.
To achieve smoking cessation, bupropion, varenicline, nico-
tine replacement, behavioral therapies, and other pharma-
cological strategies all warrant consideration. Behavioral
strategies are also useful in promoting better dietary prac-
tices, sleep hygiene, safe sex, and exercise. For some patients,
change can be achieved efficiently through support groups,
whereas others change more effectively through a one-to-
one relationship with a health care professional.

Stress-Related Physiological Response Affecting a Medical Condition
Biofeedback, relaxation techniques, hypnosis, and other stress
management interventions have been helpful in reduc-
ing stress-induced exacerbations of medical illness, includ-
ing cardiac, gastrointestinal, headache, and other symptoms.
Pharmacological interventions have also been useful (e.g., the widespread practice of prescribing benzodiazepines
during acute myocardial infarction to prevent stress-induced
increase in myocardial work).

Psychological Factors in Specific Medical Disorders
In the remainder of this chapter, the effects of psychological
factors on selected medical disorders are reviewed. The pri-
mary focus is on those effects for which there is reasonable
evidence from controlled studies. Space considerations preclude
inclusion of all valuable studies and all medical disorders.
Most of the early research suffers from serious method-
ological flaws, including use of small biased samples, limited
or no statistical analysis, poor (if any) controls, and retro-
spective designs subject to recall and other biases (Levenson
et al. 1990). This early work generated excitement and inter-
est in psychosomatic medicine but also produced ideas that
in retrospect were intellectually appealing but erroneous and
simplest regarding the special designation of certain diseases as psychosomatic.

Later research has shown improvements in methodol-
ogy, but problems in design and interpretation continued.
Several studies that seem to have shown significant effects of
psychological factors on medical disease have been inconclu-
sive because of nonequivalence in groups at baseline either
in medical disease severity or in treatments received (many
studies have not even monitored this possibility). Some
studies failed to attend to important potential confounding
factors such as smoking or diet. A number of studies have
measured too many psychological variables and then overly
emphasized the few “discovered” positive associations in the
published results. Failure to standardize measures of initial
psychological factors and measures of medical outcome has
also been frequent. Despite these and other critiques, a large
and growing body of disease-specific research has illumi-
nated the full range of PFAMC.

Psychological Factors in Oncology
Many health professionals and lay people believe that
psychological factors play a major role in cancer onset and
progression. The media have promoted popular ideas of
overcoming cancer through “mind over body.” Enthusiasm
for these optimistic theories and practices should be tem-
pered by the recognition that scientific evidence clarifying
the relationship between psychological factors and cancer
lags far behind. Nevertheless, there is an exciting frontier
of exploration of immune and endocrine mechanisms that
may provide a pathophysiological basis for some PFAMC in
cancer (Spiegel and Sephton 2001). In this section, aspects of
PFAMC in oncology that have received support in the
research literature are reviewed.

Mental Disorders and Psychological Symptoms
Affecting Cancer
The most active area of study has been the linking of affect-
ive states, particularly depression (as a symptom or as a
disorder), with the onset and course of cancer. An early
large epidemiological study of more than 2000 employees
of Western Electric reported that depressive symptoms were
associated with a higher than normal frequency of cancer
and twice as high a risk for death from cancer (Shekelle
et al. 1981). Later epidemiological studies, however, have gen-
erally not found such associations (Vogt et al. 1994, Gallo et
al. 2000). Recent prospective large cohort studies found no
effect of depression on breast cancer risk in Finnish women
(Aro et al. 2005) or of any cancer risk in Danes (Bergelt
et al. 2005). The interpretation of epidemiologic studies is
complex with many methodological problems, discussed in
detail elsewhere (Levenson and McDonald 2002).

Besides epidemiologic studies, other research has
focused on the impact of affective states on outcome in
cancer patients. In the year after diagnosis of breast cancer,
half of women have clinically significant depression, anxiety,
or both (Burgess et al. 2005). Emotional distress may predict
lower survival with lung cancer (Faller et al. 1999), as may

1760  Section VI • Disorders
anger in metastatic melanoma patients (Butow et al. 1999). Other studies have found positive, negative or mixed associations between depression and mortality in cancer patients (Garssen and Goodkin 1999, Levenson and McDonald 2002, Watson et al. 2005). Besides survival, depression in cancer patients may result in poorer pain control (Glover et al. 1994), poorer compliance (Ayres et al. 1994), and less desire for life sustaining therapy (Lee and Ganzini 1992).

Bereavement is a significant stressor with a variety of psychological and physiological effects including immune functions, and has been often assumed to be a risk factor in cancer onset and progression. However, most studies have not supported this. A meta-analysis of 46 studies found only a modest association between separation and loss experiences and development of breast cancer (McKenna et al. 1999). A large prospective cohort study comparing cancer patients found no evidence that death of a child influences survival (Li et al. 2003). In another study, bereavement (death of a son) after, but not before, diagnosis of cancer was associated with accelerated demise (Levav et al. 2000). The evidence to date is that neither cancer onset nor progression have been clearly shown to be influenced by bereavement.

Personality Traits or Coping Style Affecting Cancer
A large body of literature has described cancer patients’ degree of emotional expressiveness and its purported effect on prognosis. Descriptive case reports began appearing in the 1950’s, noting shorter survival in patients with depressed, resigning characteristics compared with patients who were able to express more negative emotions, such as anger. Using a variety of conceptualizations of the “expressive” versus “repressive” dichotomy, in an assortment of cancer types, several investigators have found reduced cancer risks in the more expressive subjects (Temoshok et al. 1985, Kune et al. 1991). Other clinical studies, again with varying definitions and study populations, have not supported an influence of this personality style (Cassileth et al. 1985, Buddeberg et al. 1991). While one recent cohort study showed that neuroticism is negatively associated with cancer survival (Nakaya et al. 2006), most epidemiological studies have not supported a relationship between personality variables and cancer occurrence or mortality (Shekelle et al. 1981, Nakaya et al. 2005, Hansen et al. 2005).

Breast cancer patients who demonstrated a “fighting spirit” or who used denial, were found to have a higher survival rate than those with stoic acceptance or expressed hopelessness and helplessness (Greer et al. 1979). However, a recent study with longer follow-up indicated that a high fighting spirit confers no survival advantage (Watson et al. 2005). Fighting spirit did appear to predict longer survival after bone marrow transplantation for leukemia (Tschuske et al. 2001).

Other Psychological Factors in Cancer
An enormous literature documents the adverse effects of maladaptive health behaviors as risk factors for the development of various cancers, especially smoking but also excessive alcohol use, unsafe sex, and dietary practices. Relatively less research has examined the effects of interpersonal variables on cancer, but there is some evidence that the quality of relationships may affect cancer onset and its course (Graves et al. 1991, Waxler-Morrison et al. 1991). Social relations and social support and their effects on cancer patients (as with other diseases) are complex phenomena and may vary with cancer site and extent of disease (Decker 2007).

A number of human studies have shown an increased frequency of stressful life events preceding the onset of cervical, pancreatic, gastric, lung, colorectal, and breast cancer (see Levenson and McDonald 2002 for review). Some research has tentatively linked life stressors with cancer recurrence or progression, although not unequivocally (Ramirez et al. 1989). Many other studies have failed to find any association between preceding stressful life events and cancer onset, relapse, or progression (Nielsen and Gronbaek 2006, Bergelt et al. 2006, Maunsell et al. 2001).

Psychosocial Intervention and Cancer Outcome
A number of studies have shown improvement in the quality of life in cancer patients receiving group therapy, including improved mood and vigor, decreased pain, and better adjustment (Trijsburg et al. 1992, Andersen 1992, Fawzy et al. 1993, Spiegel et al. 1981, Goodwin et al. 2001). The possibility that a psychological intervention might improve longevity in metastatic breast cancer patients was exciting, supported initially by some studies (e.g., Spiegel et al. 1989, Cunningham et al. 1998), but not by the definitive replication study (Goodwin et al. 2001) as well as some others. Thus the evidence to date suggests that patients with cancer can be told that group therapy contributes to living better, not necessarily longer.

Psychological Factors in Cardiology
Coronary Disease
One of the most studied examples of PFAMC is the type A behavior pattern and its relationship to CAD. Type A is a complex set of traits including impatience, hostility, intense achievement drive, and time urgency, among others. Strong epidemiological evidence that type A behavior pattern was a risk factor for the development of CAD first appeared over 30 years ago (Rosenman et al. 1975). However, the relationship between type A behavior pattern and coronary disease has come under serious question. Later epidemiological studies have not strongly supported type A behavior pattern as a coronary risk factor, and most angiographic studies have failed to find an association between type A behavior and the extent of CAD (Dimsdale 1988). Whereas global type A behavior ratings are probably not reliable predictors of CAD outcome, a component may be. Of the type A traits, hostility has been the most consistently associated with increased cardiac events and mortality (Boyle et al. 2004). A number of relatively small, short-term studies have demonstrated that type A behavior can be targeted for structured treatment and can possibly be modified (Levenkron and Moore 1988). Only one large randomized study has been reported, in which men were assigned after myocardial infarction to receive cardiac group counseling with or without type A counseling. The CAD recurrence rate was 7.2% in the group that received type A behavior counseling and 13% in the control subjects, with no difference in mortality (Friedman et al. 1986).

Although it has received less media attention than type A, the evidence that depression is a risk factor affecting both
the onset and course of CAD is stronger than that for type A (Musselman et al. 1998, Glassman and Shapiro 1998). The weighting of depression as an independent risk factor in CAD has had to adjust for its interrelationships with other risk factors, especially smoking. Depression in CAD is associated with increased morbidity and mortality, which cannot be accounted for by other variables including severity of cardiac disease (Frasure-Smith et al. 1993, Carney et al. 2003). Frasure-Smith et al. (1993) reported a fourfold increase in mortality 6 months after myocardial infarction in patients with major depression compared to those without depression. In a large epidemiologic study, major depression tripled the relative risk of cardiac mortality in those without heart disease, and quadrupled it in those who had heart disease (Penninx et al. 2001). Depression is also associated with an increased risk for serious arrhythmia. The severity of depressive symptoms has more impact on disability than does the number of stenosed coronary arteries (Sullivan et al. 1997). In the Heart and Soul Study of over 1,000 outpatients with stable CAD, depressive symptoms strongly (negatively) contributed to health status, including symptom burden, physical limitation, quality of life, and overall health, but measures of ischemia and ejection fraction did not contribute (Ruo et al. 2003).

Patients with severe mental disorders have about twice the prevalence of the classic risk factors for CAD (Birkenaes et al. 2006). While the mechanisms by which depression increases morbidity and mortality in CAD has not been firmly established, evidence is mounting regarding depression’s adverse effects on heart rate variability, autonomic imbalance and arrhythmia, and platelet activation (Carney et al. 2001, Musselman et al. 2000, Markovitz et al. 2000). Proinflammatory mediators associated with depression may also be a contributor to CAD (Parissis et al. 2004). In CAD, depression also reduces functional capacity (Wells et al. 1989), amplifies somatic symptoms (especially pain) (Light et al. 1991) and reduces motivation and compliance with medication, lifestyle change, and cardiac rehabilitation (Ziegelstein et al. 2000, Carney et al. 1995). Multicenter intervention studies have demonstrated the efficacy of treating depression in CAD but have not as yet shown that such treatment can improve medical outcomes (e.g., the Sertraline Antidepressant Heart Attack Randomized Trial (SAD-HART) (Glassman et al. 2002) and the Enhancing Recovery in Coronary Heart Disease (ENRICHD) study (Writing Committee for the ENRICHD Investigators 2003).

One specific mechanism by which psychological factors can affect CAD has been demonstrated experimentally. Silent myocardial ischemia (ischemic changes on the electrocardiogram without symptoms of angina) can be precipitated by acute mental stress (Rozanski et al. 1988). Those who experience it are twice as likely to have major cardiac events compared to those who do not (Jiang et al. 1996). Silent ischemia may be partly a consequence of cognitive or defensive traits such as denial, hyposensitivity to somatic sensation, or systematic misperception of angina (Barsky et al. 1990). Psychological stress also changes the balance between procoagulation and fibrinolysis (von Kanel et al. 2001). Psychological factors may also affect outcome in CAD via differences in health care received. After myocardial infarction, patients with mental disorders are less likely to undergo cardiac catheterization and coronary revascularization than those without mental disorder (Druss et al. 2000).

Although the diagnosis and treatment of anxiety in patients with cardiac symptoms have received much attention, there has been less examination of anxiety as a risk factor affecting CAD. Increases in myocardial infarction and/or sudden death have been documented in epidemiologic studies of populations undergoing missile attacks, earthquakes, and other disasters (Krantz et al. 2000). Generalized anxiety disorder is associated with CAD risk factors even after controlling for depression (Barger and Sydeman 2005). Phobic anxiety predicts risk of ventricular arrhythmias and deaths from coronary heart disease (Kawachi and Berkman 2003, Watkins et al. 2006). The INTERHEART study of 11,000 patients with first myocardial infarction (MI), compared to 13,000 controls from 52 countries found higher rates of stress factors (work, home, financial, and major life events) associated with increased risk of MI (Rosengren et al. 2004). Anxiety following MI may lead to more frequent readmission for unstable angina and more MI recurrences (Frasure-Smith et al. 1995), as well as higher mortality (Moser and Dracup 1996). Anxiety’s adverse effects on CAD outcome may occur via effects on heart rate variability, QT prolongation, or other autonomically-mediated phenomena, like the stress-induced silent ischemia described above (Januzzi et al. 2006).

Denial is another common and significant psychological factor in patients with coronary disease. Denial may prevent individuals from acknowledging acute cardiac symptoms and promptly seeking medical care. The length of delay between the onset of symptoms of a myocardial infarction and hospitalization is a powerful predictor of morbidity and mortality, so denial at the onset of symptoms has an adverse impact on acute coronary disease. In contrast, denial during hospitalization may have adaptive value, perhaps even reducing morbidity and mortality (Levenson et al. 1989, Levine et al. 1987).

There are other psychological factors deserving of the study. Women with severe marital stress had triple the risk of recurrent coronary events than those without marital stress (Orth-Gomer et al. 2000). Many studies have also examined maladaptive health behaviors as risk factors in coronary disease, with the effects of smoking better established than those of sedentary lifestyle, obesity, or specific diet. The effects of psychopathology and of smoking on heart disease are easily confounded, as persons with psychiatric disorders are overall twice as highly to smoke as others, with the increased risk found with all the major anxiety, mood, and psychotic disorders (Lasser et al. 2000).

**Arrhythmias**

There is evidence that psychological stressors can also play an important role in precipitating serious ventricular arrhythmias. Sudden cardiac death after psychological distress has been reported anecdotally for a long time but is difficult to study scientifically. There was an increase in life-threatening ventricular arrhythmias in New York City following the attack on the World Trade Center (Steinberg et al. 2005). A systematic review of published cases of ventricular fibrillation in patients without known cardiac disease could identify preceding psychological distress in 22% (Viskin and Belhassen 1990). A review of 96
published studies investigating psychosocial risk factors for arrhythmia found that 92% were positive (Hemingway et al. 2001).

Congestive Heart Failure
Depression is especially common in patients with congestive heart failure (Koenig 1998, Jiang et al. 2001). In patients hospitalized for congestive heart failure, major depression is independently associated with increased mortality and readmission 3 and 12 months later (Jiang et al. 2001).

Hypertension
The stress-related physiological response subcategory of PFAMC is particularly relevant to hypertension. There are some data suggesting that blood pressure reactivity to stress is a risk factor for the development of hypertension (Pickering and Gerin 1988) and may influence progression of disease as well (Shapiro 1988). Many studies have examined relationships between personality, coping style, blood pressure reactivity, and hypertension, but conflicting results and methodological limitations have precluded any consensus conclusions (Friedman et al. 2001). Findings regarding the effects of stress, anger, hostility, or anxiety on blood pressure in normotensive individuals are not necessarily relevant to clinical hypertension. Some epidemiologic studies have found depression and/or anxiety symptoms predictive of later development of hypertension even after controlling for confounding factors (Davidson et al. 2000, Jonas et al. 1997). A large prospective population-based study found a dose-response relationship between the Type A behavior factors of time urgency/impatience and hostility and increasing risk for hypertension (Yan et al. 2003). Several measures of occupational stress appear to be independent risk factors for hypertension in the general population (Levenstein et al. 2001). Some of the apparent association between psychological distress and hypertension is chiefly attributable to health risk behaviors (obesity, smoking, alcohol, and sedentary lifestyle). (Levenstein et al. 2001).

Psychological Factors in Endocrinology
Diabetes Mellitus
Despite some of the early psychosomatic literature, there is no unique diabetic personality, but physicians who take care of diabetic patients attest to a close interrelationship between psychological factors and glucose control. That psychological stress can adversely affect glucose control in diabetics seems expectable because the hormones of the stress response are part of the counterregulatory response to insulin. A number of studies have shown that glycemic control is poorer in those diabetic patients who have more perceived stress (Garay-Sevilla et al. 2000, Lloyd et al. 1999, Herpertz et al. 2000). As assessed by hemoglobin A1c, metabolic control was poorer in depressed children (Lernmark et al. 1999), and in adult depressed type 1 but not type 2 diabetics (De Groot et al. 1999, Van Tilburg et al. 2001). A meta-analysis of 24 studies concluded that depression consistently is associated with a small-to-moderate increase in hyperglycemia in both type 1 and type 2 diabetes (Lustman et al. 2000). Depression is associated with more diabetic complications (Lloyd et al. 1992, and De Groot et al. 2001). More recently, depressed diabetics have more severe diabetic symptoms (Ludman et al. 2004), more disability (Von Korff et al. 2005), greater mortality (Katon et al. 2005), and higher health care costs (Simon et al. 2005) than other diabetics. Most such research has been retrospective or cross-sectional, leaving it unclear which came first (poor metabolic control and complications or the psychological factor) and what is the relationship between them.

When psychiatric illness antedates and adversely affects the course of diabetes, it may be mediated by noncompliance (diet, medication, activity, visits to the physician, self-care) (Ciechanowski et al. 2000, Van Tilburge et al. 2001) or by neurohumoral mechanisms. The adverse effects in diabetic control cannot all be attributed to noncompliance. Psychological stress administered under laboratory conditions can impair glucose control in both insulin-dependent (Gonder-Frederick et al. 1990) and noninsulin-dependent diabetes (Goetsch et al. 1993). One potential explanation is that depression, anxiety, and stress are often associated with increases in cortisol and other counterregulatory hormones opposing the action of insulin.

Small randomized controlled trials have demonstrated improvements in glucose control in diabetics receiving psychological interventions (Delamater et al. 2001, Grey et al. 2000). The Pathways Study, the most comprehensive clinical trial of enhanced treatment for depression in diabetics, demonstrated that it improved the quality of care and outcomes for depression but did not result in improved glycemic control (Katon et al. 2004). Antidepressants are effective in the treatment of depression in diabetics, but can cause increases or decreases in blood glucose themselves. Deterioration in glucose control in schizophrenic diabetics can be due to atypical antipsychotic drugs, but diabetes was also a major problem for schizophrenics before their advent, presumably because of obesity (a side effect of almost every antipsychotic), unhealthy diet, and poorer health care (Dixon et al. 2000). Optimal management of diabetes requires a degree of organization very difficult for most patients with schizophrenia.

Thyroid Disease
It is well established that too little or too much thyroid hormone can result in disturbances in mood and activity. In the other direction, the effects of emotion and stress on thyroid function, although long a focus of interest, are less well established. Parry’s original report in 1825 described a woman who had hypothyroidism four months after she accidentally fell down stairs in a wheelchair. A number of classic studies reported a relationship between antecedent traumatic stress and the onset of thyrotoxicosis, particularly as part of Graves’ disease. However, these studies were retrospective, uncontrolled, and too methodologically flawed by current standards to support the validity of such a link. Later studies have supported stressful life events as a risk factor for Graves’ disease (e.g., Santos et al. 2002). Two prospective studies in patients newly diagnosed with Graves’ disease found that after adjusting for confounding variables, psychological stress adversely affected the response to treatment and prognosis (Fukao et al. 2003, Yoshiuchi et al. 1998a). Psychological stress may also be a result of less optimal control of hyperthyroidism (Yoshiuchi et al. 1998b).

Whereas there has been little well-substantiated evidence of the impact of psychological factors on thyroid disease,
alterations in thyroid function or its hypothalamic-pituitary control have been demonstrated in relation to affective disorders, schizophrenia, and posttraumatic stress disorder (Mason et al. 1994). Depression has been most studied, revealing a variety of thyroid abnormalities, most frequently a relative increase in thyroid hormone without changes in the activated (triiodothyronine) and inactive (reverse triiodothyronine) forms and a blunting of the thyroid-stimulating hormone response to thyrotropin-releasing hormone (Goodwin and Jamison 1990). There is not agreement regarding the relationship between these endocrine changes and depressive pathophysiological processes, and it remains unknown whether depression modifies endocrine measures in clinical thyroid disease.

**Psychological Factors in Pulmonary Disease**

Although asthma was once regarded as a classic psychosomatic disorder, it is currently viewed as a primary respiratory disease with varying immunological and autonomic pathophysiological changes. Many physicians still believe that psychological factors play an important role in the precipitation and aggravation of asthma, particularly anxiety. One must remember, however, that respiratory distress itself causes a wide array of anxiety symptoms (panic attacks, generalized and anticipatory anxiety, phobic avoidance), and most of the drugs used to treat asthma have anxiety as a potential side effect. Brittle asthmatic patients, like brittle diabetic patients, are more likely to have current or past psychiatric disorder (particularly anxiety disorders) than are other asthmatic individuals, but which came first has not been established. In a large population-based sample of adults, asthma was associated with a significantly increased likelihood of anxiety disorders (especially panic, generalized anxiety disorder, and phobias) and affective disorders (Goodwin et al. 2003). There is no typical personality type susceptible to development of asthma. Anxiety and depression are associated in asthmatic patients with more respiratory symptom complaints but no differences in objective measures of respiratory function (Rietveld et al. 1999). Asthma symptom severity increased in New York City following the terrorist attacks on September 11, 2001, and PTSD was a significant predictor of the increase (Fagan et al. 2003). Psychological factors and psychosocial problems in hospitalized asthmatics were a more powerful predictor of which ones required intubation than any other examined variable (e.g., smoking, infection, prior hospitalization, etc.) (Le Son and Gershwin 1996). Psychological morbidity is associated with high levels of denial and delays in seeking medical care, which may be life-threatening in severe asthma, (Miles et al. 1997), as well as less medication adherence and consequently poorer control of asthma (Chuley and Cochrane 2001). Not surprisingly then, psychopathology in severe asthmatics is associated with increased health care utilization, including hospitalizations, and outpatient and emergency room visits, independent of asthma severity (Ten Brinke et al. 2001).

Similar problems exist in interpreting relationships between anxiety or depression and other chronic obstructive pulmonary diseases (chronic bronchitis, emphysema). Depression and anxiety are common in chronic obstructive pulmonary disease (COPD) (Yohannes et al. 2000, Aydin and Ulusahin 2001), though this partly reflects their increased prevalence in past or current smokers. As in asthma, psychological distress in COPD amplifies dyspnea without usually causing changes in objective pulmonary functions. Depression and anxiety do lead to lower exercise tolerance (Withers et al. 1999), noncompliance with treatment (Bosley et al. 1996), poorer health status (Gudmundsson et al. 2006 and increased disability in COPD (Aydin and Ulusahin 2001). Anxious COPD patients are more likely to be hospitalized (Smoller et al. 1996) and rehospitalized (Gudmundsson et al. 2005). Depression in outpatients suffering from COPD may even be an independent predictor of mortality (Stage et al. 2005). Smoking is a well-established maladaptive health behavior causing and exacerbating chronic obstructive pulmonary disease, and its elimination is the most beneficial intervention available.

**Psychological Factors in Rheumatoid Arthritis**

Rheumatoid arthritis (RA) was also once thought to be a psychosomatic disorder, but studies in the modern era have provided little or no support for this belief. There is no particular personality type susceptible to development of rheumatoid arthritis. Earlier research suggesting that stressful like events play a role in the development or onset of RA has not been supported by subsequent studies (e.g., Carette et al. 2000). Psychological factors and disease manifestations account for comparable proportions of disability in RA (Escalante and del Rincon 1999). Psychosocial morbidity in RA results in more pain, poorer quality of life, more joint surgery, lower compliance, and increased use of health care resources (Newman and Mulligan 2000, Wolfe 1999, Kroll et al. 1999).

Depression has been the most frequently studied psychological disturbance in rheumatoid arthritis; depression is very common, as in other chronic medical conditions (Soderlin et al. 2000). Depression appears to adversely affect outcome in rheumatoid arthritis, aggravating chronic pain, increasing health care use, and increasing social isolation (Dickens et al. 2007). A recent large longitudinal study found depression to be an independent risk factor for mortality in patients with RA (Ang et al. 2005). Randomized controlled trials of antidepressants in depressed RA patients demonstrate improvements in pain, morning stiffness, and disability in addition to depression (Bird and Broggiini 2000, Ash et al. 1999).

Passive, avoidant, emotion-laden coping strategies (e.g., wish-fulfilling fantasy, self-blame) are associated with poorer adjustment to illness in RA compared with active, problem-focused coping (e.g., information seeking, cognitive restructuring) (Covic et al. 2000). RA patients with high helplessness are more likely to receive psychotropic, analgesic, and anti-inflammatory drugs and to be less adherent with treatment than those with low helplessness (Stein et al. 1988). Patients with RA may be more vulnerable to stress-induced increases in immune and endocrine function (Hirano et al. 2001). A randomized controlled trial of cognitive–behavioral therapy as an adjunct to standard treatment in recently diagnosed patients with RA showed it efficacious in reducing both psychological and physical morbidity (Sharpe et al. 2001).

**Psychological Factors in Neurology**

Depression is frequent after stroke, particularly in the acute phase during hospitalization and the first few weeks after...
stroke (Astrom et al. 1993). The presence of depression is associated with poorer outcomes, including higher later mortality (House et al. 2001), and functional status is improved with treatment of depression after stroke (Lipsky et al. 1984). A negative attitude after stroke (i.e., feeling there is nothing one can do to help oneself) is associated with decreased survival (Dennis et al. 2000). Research has focused on depression as a complication of stroke but there is also evidence that depression and other psychological factors constitute risks for stroke, consistent with widespread lay and folk beliefs regarding stress and stroke. In a longitudinal prospective epidemiological study, depression appeared to significantly predict greater stroke frequency, but the finding disappeared when other significant predictors were taken into consideration (e.g., age, sex, smoking, hypertension, diabetes) (Colantonio et al. 1992). Later studies have found depressive symptoms increase the risk of stroke in older adults (Simons et al. 1998, Everson et al. 1998, Ostir et al. 2001). Depression appears to be an independent predictor of increased health care use after stroke (Jia et al. 2006) and is also associated with poorer functional recovery (Nannetti et al. 2005). As with many other medical illnesses, stroke patients with extensive social support have better functional outcomes than those who do not have such support (Colantonio et al. 1993).

Depression is common in Parkinson’s disease, may antedate the development of motor symptoms, and is associated with cognitive dysfunction (Holroyd et al. 2005, Errea and Ara 1999). Physicians observe that depression and other psychological factors interact to affect the course and outcome of Parkinson’s disease, with depression resulting in impairment of functional capacity, but not motor function in Parkinson disease (Holroyd et al. 2005). Depression is also common and erodes quality of life in multiple sclerosis (MS) (Fruevald et al. 2001) and in epilepsy (Mensah et al. 2006, Barry et al. 2000). The study of depression as an independent risk factor affecting the onset or course of neurological diseases is challenging because depression may also be a direct physiologically-mediated consequence of the disease, a psychological reaction to the illness, or a complication of pharmacotherapy (Zorzon et al. 2001). In MS, depression may increase and its treatment decrease, production of proinflammatory cytokines (Gold and Irwin 2006, Mohr et al. 2001). Depression is especially difficult to study in MS because of its uncertain relationship to the MS-fatigue syndrome (Bakshi et al. 2001).

Patients with chronic migraine headaches have often been described as having a “typical” personality characterized as conscientious, perfectionistic, ambitious, rigid, tense, and resentful, but controlled studies have not supported any consistent conclusion. Specific personality traits in migraine appear more likely to be a consequence rather than a cause of suffering from recurrent headaches (Stronks et al. 1999). Migraine and depression are highly comorbid (Lipton et al. 2000). Migraine patients with anxiety and depression reported poorer treatment efficacy and satisfaction with treatment (Lanteri-Minet et al. 2005). A community-based survey found more personality disturbance and 2.5 times more psychological distress in migraine sufferers than in matched control subjects, but there was no relationship between headache frequency and the severity of psychological distress or personality abnormality (Brandt et al. 1990).

### Psychological Factors in End Stage Renal Disease

Studies of the influence of psychological factors upon the course of end-stage renal disease (ESRD) have nearly all focused on depression or noncompliance. There has been essentially no investigation of psychological factors in chronic renal failure before end stage.

Depression has been shown to be a better predictor of (shorter) survival than age or pathophysiological variables in dialysis patients (Burton et al. 1986, Shulman et al. 1989), although negative results have also appeared (Kutner et al. 1994). Depression is associated with smoking, alcoholism, and other forms of substance abuse that are highly prevalent in ESRD patients (Hegde et al. 2000). Subsequent studies have done a better job of controlling for ESRD severity and other potential confounds, and still find that depression predicts higher mortality (Kimmel et al. 2000). One prospective study in peritoneal dialysis patients found higher depressive symptoms associated with a greater risk of peritonitis, after controlling for other risk factors (Troidle et al. 2003). In hemodialysis patients, level of depression symptoms was a unique and significant predictive risk factor for the subsequent decision to withdraw from dialysis (McCade-Montez 2006).

Other outcome studies have focused on the impact of noncompliance in ESRD (Manley and Sweeney 1986). Compliance is a complex, multidimensional array of behaviors, and its relationship with health outcomes in dialysis patients is difficult to study. Thus, whereas effects of noncompliance on dialysis patients’ outcomes are well recognized by physicians, they have not been adequately characterized empirically. Nevertheless, the widespread belief among physicians and nurses that noncompliance results in worse outcomes including higher mortality in ESRD is supported by a large multicenter study (Leggat et al. 1998). The chronic overuse of nonsteroidal antiinflammatory agents and analgesics is a maladaptive health behavior recognized as a fairly common contributing cause of chronic renal insufficiency (Fored et al. 2000). One psychosocial intervention outcome study in ESRD found that patients who participated in a support group lived longer than nonparticipants even after multiple psychosocial and psychological variables were controlled, but this was a naturalistic nonrandomized study (Friend et al. 1986).

### Psychological Factors in Gastroenterology

#### Inflammatory Bowel Disease (IBD)

Ulcerative colitis is another disorder that was described in the early literature as a psychosomatic disease, but no specific psychogenic factor contributing to the development of ulcerative colitis or Crohn’s disease has ever been substantiated. As with other chronic medical diseases, patients with more psychological distress tend to be those with more severe physical disease and poorer functional capacity, but the causal relationships are not clear (Sewitch et al. 2001). Psychological stress does appear to aggravate both symptom complaints and mucosal disease activity in ulcerative colitis (Levenstein et al. 1994). Depression may predict relapse in IBD (Mittermaier et al. 2004, Kurina et al. 2001). Disability and distress in patients with IBD are increased by the presence of a concurrent psychiatric disorder.
Peptic Ulcer Disease (PUD)

The direct effects of emotion on gastric secretion were first demonstrated in 1833 by William Beaumont, who made observations through a Canadian lumberjack’s gastric fistula resulting from an injury. Early psychosomatic investigators studied the role of specific psychological risk factors for duodenal ulcer. In a classical empirical study, Weinert et al. (1957) successfully predicted which men in a large cohort of Army draftees would have duodenal ulcers by combining psychological criteria with the biological criterion of high baseline pepsinogen secretion. Since then, the central role of the bacterium Helicobacter pylori in the etiology of PUD has been clearly established. Many physicians have consequently discarded the longstanding belief that stress causes PUD, and concluded that PUD is an infectious disease, except when attributable to nonsteroidal anti-inflammatory drugs (NSAIDS). Nevertheless, psychological factors appear to be a significant part of the explanation for why only a fraction of those colonized by H. pylori or taking NSAIDS develop ulcers. Psychological stress is an independent risk factor for the development (Rosenstock et al. 2003) and recurrence of duodenal ulcer (Levenstein et al. 1995a). The frequency of peptic ulcer increases following catastrophic stressful events, including bombardment, earthquake, economic crisis, or being a prisoner of war or “boat people” refugee (Levenstein 2000). Overall, psychosocial factors contribute to 30–65% of peptic ulcers (Levenstein 2000), and are most likely to be present in patients with duodenal ulcers who do not have conventional medical risk factors (H. pylori, NSAIDS) (Levenstein et al. 1995b). Occupational stress, family conflicts, depression, maladjustment and hostility also are prospectively associated with PUD (Levenstein et al. 1997).

Psychological factors appear to influence PUD through both health risk behaviors (smoking, alcohol abuse, overuse of NSAIDS, poor diet, poor sleep) and psychophysiological mechanisms (pepsinogen and acid secretion, altered blood flow, impairment of mucosal defenses, and slowing of healing related to the action of cortisol) (Levenstein 2000).

Psychological Factors in Dermatology

Dermatologists routinely observe the effect of psychological factors, especially anxiety, in the aggravation of a wide variety of dermatological conditions. There are few systematic studies, and perhaps the most important relationships are not uniquely related to particular dermatological disorders. Both anxiety and depression appear to worsen pruritus (itching). So-called neurotic excoriation complicates many dermatological disorders and is aggravated by anxiety, depression, and other behavioral factors (Gupta et al. 1996). That so many skin diseases appear to be precipitated or exacerbated by psychological stress also suggests a nonspecific impairment of cutaneous function. There is now evidence in both animals and humans that stress negatively affects skin’s function as a permeability barrier (Garg et al. 2001).

Dermatologists clinically observe important relationships between psychological factors and urticaria, angioedema, atopic dermatitis, hyperhidrosis, acne, and psoriasis, (Arnold 2005) but controlled studies are lacking. Excessive sun exposure is a maladaptive health behavior contributing to skin cancer and various other dermatological conditions.

Psychological Factors Affecting Infectious Diseases

HIV infection is the most destructive example of unsafe sexual practices as a maladaptive health behavior contributing to development and transmission of an infectious medical condition. Once contracted, HIV infection appeared to be a likely candidate for important effects of psychological factors, because of the work demonstrating changes in normal immune function after stress, bereavement, and depression. This has been a very active field of investigation with most but not all studies finding adverse effects of stress and depression on disease progression, immune function, and mortality in patients with HIV infection (Ironson et al. 2005; Leserman et al. 2002; Farinpour et al. 2003; Golub et al. 2003; Psychod et al. 2000; Sewell et al. 2000).

Psychological factors influence other infectious diseases as well, including the common cold (Cohen 2005), pneumonia (Mehr et al. 2001), genital herpes (Levenson et al. 1987), and recurrent urinary tract infections (Hunt and Waller 1992). A number of studies have convincingly shown that psychological stress suppresses the secondary (but not primary) antibody response to immunization (Cohen et al. 2001).
Psychological Factors in Obstetrics
While much more attention has been paid to postpartum depression, antepartum depression also adversely affects pregnancy outcome. In a number of studies both antepartum anxiety and depression have been associated with growth retardation and premature birth (e.g., Neggers et al. 2006), resulting in lower birth weights, but potential confounding factors have often not been adequately controlled for, and not all studies have replicated these findings (e.g., Andersson et al. 2004). Whether depression and other psychological dysfunction cause poorer obstetric outcomes through poor nutrition, substance abuse (including tobacco), poor adherence or no prenatal care and/or, physiological (hormonal, vascular) effects require further investigation.

Psychological Factors in Infertility
Psychological factors are likely to affect fertility because frequency and timing of sexual intercourse are important determinants of fertility. Nonconsummation, avoidance of intercourse, vaginismus, and psychogenic amenorrhea are attributable to psychological origins. Psychogenic causes do not account for most male impotence but do play a role in many cases (Schneid-Kofman and Sheiner 2005). In general, measures of stress, but not of psychopathology, have been associated with infertility (Greil 1997). This is a particularly complex subject for study because it involves potential psychological factors in both members of the couple and interactions between them as well as their effects on sexual behavior and fertility (Cwikel et al. 2004). Psychological factors have also been identified as predictors of drop out from infertility treatment (Smeenk et al. 2004). Most psychological distress seen in infertile couples is a result of, rather than a cause of, infertility.

Clinical Vignette 1
Ms. A, a 46-year-old married attorney, was referred for psychiatric evaluation by her gastroenterologist, who follows her for long-standing IBS. She has had IBS since the age of 20 years, with complaints of intermittent constipation, diarrhea, crampy abdominal pain, and bloating. She feels that these symptoms have gradually worsened, particularly in the last month. She describes a highly pressured job and a stressful marriage. She has specifically noticed a precipitous increase in intestinal symptoms immediately after arguments with her husband and when facing deadlines at work. Three months ago, she developed depressed mood, early morning awakening, anorexia, fatigue, crying spells, impaired concentration, irritability, and preoccupation with thoughts of ill health. Her family physician diagnosed major depression and prescribed amitriptyline, which was discontinued after it caused worsening of her constipation. Her psychiatrist then tried fluoxetine (discontinued because of diarrhea) and trazadone (too sedating). She then responded well to nortriptyline with disappearance of the symptoms of depression and improvement in her IBS. However, severe IBS symptoms continued to follow the frequent marital arguments. The psychiatrist asked the patient to invite her husband to join one of their sessions so that marital issues could be further explored. He did so, resulting in the discovery that her husband was himself significantly depressed. He was referred to another psychiatrist for treatment, the marital discord abated, and her IBS symptoms returned to a manageable level.

In this clinical vignette, the patient had features of both mental disorder (major depressive disorder) affecting a general medical condition and stress-related physiological response affecting a general medical condition. Treatment included individual psychotherapy and antidepressant medication as well as marital assessment and intervention. Pharmacotherapy required modification because of gastrointestinal sensitivity to side effects.

Clinical Vignette 2
Mr. B is a 60-year-old married judge with CAD. He was referred for psychiatric evaluation by his cardiologist because he declined coronary artery bypass surgery despite strong and repeated recommendations for surgery by the cardiologist. The cardiologist perceived that the patient’s resistance to surgery was not due to lack of information or understanding.

Mr. B had no acute psychiatric symptoms, although he had several lifelong phobias including fear of cats, fear of being buried alive, and claustrophobia (recent episodes in the hospital elevator and during magnetic resonance imaging). His only previous psychiatric contact was some marital therapy 20 years earlier. His CAD was severe, with two myocardial infarctions and recurrent malignant arrhythmias. He continued to have recurrent angina despite maximal medical management; his pain occurred mainly at night as “a predictable consequence of pushing too hard at work” (he typically worked 12-hour days). He had also had a stroke 3 months ago, from which he had made a complete recovery with no sequelae. Twenty years earlier, he had surgery for a renal stone that was complicated postoperatively with five pulmonary emboli. He said that he has had “eight near-death experiences” amidst his various illnesses.

Mr. B was eager to discuss his reluctance to have coronary bypass surgery. He had not decided against the surgery but had been unable to reach a decision. He brought to the appointment with the psychiatrist a two-page list of arguments for and against surgery and other variables that could influence the decision and outcome. He was aware that he was approaching the question of surgery with the same style of carefully balanced consideration of all sides of an issue that he prided himself on in his occupation as a judge. He worked longer days than his colleagues because he believed it took more time to make fair, proper, and legally correct decisions. His analysis of the pros and cons of surgery, as well as intervening factors affecting and affected by the decision, appeared to the psychiatrist to be well informed, accurate, flexible, and appropriate. There was no evidence of rigidity in his thinking, premature closure, or distorted perceptions. Whereas the thought processes were logical, they had not enabled him to reach a decision, despite extensive discussions with the cardiologist over a period of months. He was aware that this was another decision in his life that was taking much longer than average, but he thought it could not be resolved any other way.

This case represents an example of personality trait or coping style affecting a general medical condition. His obsessional style was largely adaptive in his chosen occupation, although it reduced his efficiency. Now confronted with a major health care decision, and mindful of major complications he had suffered after surgery in the past, the need
to weigh all sides of an issue had paralyzed his decision-making. The presence of phobias in his history raised the possibility of these too affecting his decision-making, but he denied feeling fearful of the surgery, anesthesia, intubation, and the like. The anxiety he was experiencing was entirely focused around making the right decision.

Ziegelstein RC, Fauerbach JA, Stevens SS, et al. (2000) Patients with depression are less likely to follow recommendations to reduce cardiac risk during recovery from a myocardial infarction. Archives of Internal Medicine 160, 1818–1823.

Introduction
The discovery of the antipsychotic effect of chlorpromazine in the early 1950s ushered in the modern age of psychopharmacology. Despite this milestone, optimism for treatment of schizophrenia was soon dampened by the realization that antipsychotic agents could produce significant side effects, most prominently movement disorders. Much of the subsequent research investigating new antipsychotic agents was thus motivated by a need to find effective agents with a lower propensity to cause movement disorders.

While antipsychotics may produce a variety of other side effects, movement disorders are particularly disturbing for a number of reasons. Acute movement disorders, such as dystonia and akathisia, may be excruciatingly uncomfortable. Patients in whom movement disorders develop may, in addition to experiencing subjective distress, be at increased risk for nonadherence to treatment (Diaz et al. 2004), suffer embarrassment that leads to social withdrawal, and even suffer occupational impairment in severe cases. Perhaps most disturbing is that antipsychotics can produce “tardive” or late-occurring movement disorders that may be persistent or even irreversible.

Historical Background
The presence of so-called extrapyramidal motor reactions to drugs was first described in the 1940s with reserpine. It was, however, in the early 1950s that attention was first focused on the motor effects of antipsychotic drugs. In 1952, Delay and Deniker (1968) noticed extrapyramidal signs (EPS) after treatment with the antipsychotic medication chlorpromazine. Many of these EPS appeared similar to Parkinson’s disease (PD), and some investigators proposed that the presence of EPS equated with the onset of antipsychotic benefit (Haase 1961).

Approximately 5 years after chlorpromazine proved effective for psychotic disorders, Schonecker (1957) noted the onset of orobuccal dyskinesias in patients with prolonged exposure to the drug. This condition lasted nearly 3 months after the chlorpromazine was stopped. This was in marked contrast to the Parkinsonian symptoms previously described, which had reversed upon discontinuation of antipsychotics. Similar reports soon followed in France, England, Denmark, and the US (Lohr and Jeste 1988a). The term tardive dyskinesia (TD) was first used in 1964 by Faurbye and coworkers (1964) to describe this condition. The number of reports grew rapidly in a period of years, and many of the cases were reported to be irreversible.

Classification
There are different types of movement disorders that may result from treatment with antipsychotic medications. They are often categorized according to time of onset (acute or subacute vs. late-onset, i.e., tardive). For the purpose of this discussion, we group neuroleptic-induced movement disorders into the acute/subacute disorders (acute dystonia, parkinsonism, and akathisia), tardive disorders (prototypically TD), and neuroleptic malignant syndrome (NMS). It is important to note that patients often experience more than one type of medication-induced movement disorder either concurrently or sequentially (Casey 2004). We also devote a section to the discussion of medication-induced postural tremor that predominantly focuses on lithium-induced
Informed Consent/Medicolegal Issues

The possibility of irreversible neuroleptic-induced movement disorders places significant responsibility on the prescribing psychiatrist. Careful and reasoned thought must go into the analysis of whether the benefit of treatment with a medication exceeds the risk to the patient. In general, the more a patient is able to understand the nature of his or her illness and the reason that a particular medication is being prescribed, the more likely he or she is to be adherent to treatment. When the psychiatrist does not devote adequate time to informing and instructing the patient, this may damage the physician–patient rapport by engendering mistrust of the physician (by patients prone to paranoia), with subsequent adverse clinical and/or legal consequences. Unless declared incompetent by a court of law, a patient is considered to be legally competent to consent to or refuse psychotropic medications. The only exception to this rule is when an emergency situation exists and a patient must be medicated to prevent harm to self or others. The psychiatrist must provide information to the patient or the patient’s decision-maker about the nature and purpose of the medication, its risks and benefits, alternatives to the proposed treatment, and prognosis without treatment. Obtaining a written informed consent is one way of documenting the consent process. Another way is noting in the chart a summary of the discussion with a patient (or caregiver) about the consent to neuroleptic treatment.

Physicians may hesitate to divulge the full range of medication-related risks out of fear that this will discourage adherence in patients often already averse to taking medications or that this will heighten patient anxiety about treatment. While this may happen in individual cases, a patient who has been prepared openly and honestly for possible side effects may view this discussion as evidence of the psychiatrist’s knowledge and trustworthiness and may be more likely to respond to any side effects by consulting with the physician. Physicians may also choose to conduct the informed consent process over several meetings, based on the patient’s ability to process information and his/her insight. On a final note, it may not be assumed that a patient already receiving antipsychotics prescribed by another physician has received an adequate informed consent. The process must begin anew with the new treating physician.

Although movement disorders are an important risk to weigh when choosing among antipsychotic medications (e.g., typical vs. atypical), there are many factors that make the overall risk–benefit profiles and treatment decisions less than straightforward. In general, the literature continues to expand with trials demonstrating reduced incidence of new onset neuroleptic-induced movement disorders with atypical antipsychotics and, in some cases, partial improvement of existing movement disorders caused by conventional antipsychotics. While atypical antipsychotics are not without a risk of movement disorders, their improved motor side effect profile suggests that they may be a better treatment choice in populations with increased risk for movement disorders.

Older adults represent such a population at risk for movement disorders; yet, the recent black-box warnings citing an association between atypical antipsychotics and death or cerebrovascular events in dementia patients make the safer motor side effect profiles with atypical agents less of a compelling reason to use these agents in older adults (Schneider et al. 2006). The risk of death or stroke in older adults with conventional antipsychotics is not clear. The issue is further complicated by recent evidence calling into question the relative benefits in efficacy of atypical antipsychotics versus typical agents (Lieberman et al. 2005), as well as the apparent higher risk of metabolic complications associated with some atypical antipsychotics compared to certain typical antipsychotics (Jin et al. 2004). The possibility of switching to an atypical agent should be discussed with patients maintained on a conventional agent who develop or have a high risk of movement disorders. Yet, this relative risk difference must be considered in the context of other potential adverse medication effects that may differentially occur with some atypical agents (e.g. metabolic disorders).

**ACUTE NEUROLEPTIC-INDUCED MOVEMENT DISORDERS**

**Neuroleptic-Induced Acute Dystonia**

**Definition**

This long-lasting contraction or spasm of musculature develops in conjunction with the use of antipsychotic medication. Examples include torticollis (lateral neck rotation), retrocollis (neck extension), limb torsion, forced jaw closing (trismus) or opening, tongue protrusion, opisthotonus (extension of head, neck, and paraspinal muscles in an arch), and oculogyric crisis (forceful eye deviation).

**Etiology and Pathophysiology**

The pathophysiological mechanism of neuroleptic-induced acute dystonia is largely unknown. Because no consistent pathological abnormality has been located in the brain, dystonia was often regarded in the past as a disorder of psychogenic origin. There is currently no evidence to support psychological factors as being the source of dystonia.

Abnormalities in dopamine-acetylcholine balance have been suggested as a possible mechanism because cholinergic antagonists and dopaminergic agonists seem to improve the dystonia in many patients, in contrast to...
dopaminergic antagonists, which may exacerbate or cause dystonia (Stahl and Berger 1982).

**Epidemiology and Comorbidity**

Acute dystonia is generally less common than most other extrapyramidal side effects of antipsychotics. Its frequency has been reported to range from 2 to 12% of patients taking conventional antipsychotic medication (Lohr and Jeste 1988a). For patients who receive high doses of high-potency conventional agents (e.g., haloperidol), however, the frequency may be as high as 50% (Swett 1975). Incidence of acute dystonia can probably be reduced if low-dose treatment strategies are employed. Furthermore, acute dystonia is considerably less likely to occur with atypical antipsychotic medications (i.e., less than 5% of individuals) (American Psychiatric Association 2000). However, cases of dystonia have been reported with atypical antipsychotics even in low doses (Alevisos et al. 2003, Brown 1997), so patients and clinicians should remain vigilant for this side effect even when using atypical agents.

Large doses of high-potency conventional antipsychotics (especially when administered parenterally) appear to be the most consistent risk factor reported for acute dystonia (Rupniak et al. 1986). Other factors that also predispose to dystonia are young age, male sex, and a prior dystonic reaction.

**Assessment and Differential Diagnosis**

Neuroleptic-induced dystonia (sometimes referred to as a dystonic reaction) usually begins 12 to 36 hours after a new antipsychotic is started or the dosage of a preexisting one is increased. It is unusual to see a dystonia after 2 weeks of antipsychotic treatment, and probably 90% of all neuroleptic-induced dystonias occur within the first 5 days of antipsychotic treatment (Rupniak et al. 1986). Dystonias are also possible after the sudden discontinuation of anticholinergic medications (Sachdev 2005a). Patients may report a sense of tongue “thickness” or difficulty in swallowing in the 3 to 6 hours preceding the acute dystonia (Arana and Rosenbaum 2000). Others have reported a nonspecific probulomatosus anxiety/restlessness prior to fulminant dystonia (Sachdev 2005a).

Acute dystonia presents as a sustained, painful muscle spasm that produces twisting, squeezing, and pulling movements of the muscle groups involved. A notable feature of dystonias is their consistent directionality; even though there may be an accompanying tremor, the oscillations of a dystonic tremor are asymmetrically skewed in one direction. The most common muscle groups affected are the eyes, jaw, tongue, and neck, but any muscle group in the body can be involved. On occasion, the larynx or pharynx may be involved, and this can result in rapid respiratory compromise (American Psychiatric Association 2000).

Neuroleptic-induced acute dystonias are dramatic and usually easy to diagnose. There are, however, a number of other conditions that can present similarly and need to be ruled out. Spontaneously occurring focal or segmental dystonias may persist for days to weeks independent of medication. Neurological conditions such as temporal lobe seizures, infections, trauma, or tumors can produce symptoms similar to neuroleptic-induced acute dystonia. Several hereditary neurological disorders may cause psychiatric disturbance and dystonias (e.g., Wilson’s disease, Huntington’s disease, juvenile Parkinson’s disease). Hypocalcemia may cause muscle spasms similar to dystonias. Other psychotropic medications (e.g., anticonvulsants and selective serotonin reuptake inhibitors) can cause dystonias, though less commonly than antipsychotics (American Psychiatric Association 2000).

Neuroleptic malignant syndrome (NMS) can produce muscle contractions that look similar to acute dystonia but can be distinguished by generalized “lead pipe” type of rigidity, fever, fluctuating consciousness, and unstable vital signs. Catatonia associated with an affective or psychotic disorder can be difficult to
distinguish from dystonia clinically but does not respond to the administration of anticholinergic or antihista- minic medication. Furthermore, patients with catatonia are typically not concerned about their stiffness, whereas patients with dystonia are likely to be extremely distressed (American Psychiatric Association 2000).

On occasion, an acute dystonic reaction may resemble tardive dyskinesia (TD). This is easily clarified by administering anticholinergic medications, which rapidly clear dystonia and do not affect (or may worsen) TD. Making a differential diagnosis between an acute dystonia and tardive dystonia can be difficult. Tardive dystonia (similar to TD) is a diagnosis made late in the course of antipsychotic treatment and it is generally a chronic condition compared with acute dystonia, which occurs early in the course of medication treatment and typically responds rapidly to pharmacological intervention.

Course
A neuroleptic-induced acute dystonia typically subsides spontaneously within hours after onset. However, treatment should be started as soon as the dystonia is diagnosed because the experience is typically intensely distressing to the patient, and in rare cases can induce respiratory compromise.

Treatment
It is important to note that there is no FDA-approved treatment for any medication-induced movement disorder, but a number of controlled trials, along with clinical experience, offer some guidance. The standard treatment approach for acute neuroleptic-induced dystonia is the immediate administration of an anticholinergic agent. In most cases, this medication may be administered orally, intramuscularly, or intravenously. The first dose of medication should be the equivalent of 2 mg of benztropine or 50 mg of diphenhydramine (an antihistamine with strong anticholinergic properties). This should be repeated if the first dose does not produce a robust response within 30 minutes (Lohr and Jeste 1988a). This standard approach is usually successful in resolving the dystonia. Educating patients about this side effect and the importance of seeking treatment may help to avert severe dystonias and the subsequent conditioning of patients to fear medication treatments.

In the unusual refractory case, intramuscular or intravenous anticholinergic or antihistaminic drugs should be used at more frequent dosing intervals, and consideration should be given to adding an intramuscular injection of lorazepam at more frequent dosing intervals, and consideration should be given to decreasing the previous dose of the antipsychotic or possibly switching to a low-potency neuroleptic or atypical agent if the patient has been prescribed a conventional antipsychotic. The use of prophylactic anticholinergic medication (discussed in detail later) is not fully evidence-based and not without its own adverse effects.

Neuroleptic-Induced Parkinsonism

Definition
Neuroleptic-induced parkinsonism (NIP) is defined as parkinsonian signs or symptoms (resting tremor, muscle rigidity, and Bradykinesia/akinesia) that develop in association with the use of an antipsychotic medication.

Etiology and Pathophysiology
NIP is presumed to result from blockade of postsynaptic dopamine (D 2 ) receptors in the corpus striatum causing a pathological state functionally resembling the loss of dopaminergic cells in the striatum in idiopathic Parkinson’s disease (PD). However, it is not clear whether nigrostriatal dopamine loss is adequate to explain the clinical symptoms seen in NIP or PD (Lohr and Jeste 1988a). It is possible that other biochemical abnormalities may coexist with dopaminergic depletion to produce the syndrome. A model of the neurocircuitry involved in NIP was recently described by Ossowska (2002), essentially describing overactivation of the striatopallidal pathway and inhibition of the striatonigral pathway.

Interindividual factors may influence the risk of developing NIP. The finding that NIP was associated with echogenicity of the substantia nigra on transcranial ultrasound suggests that certain people may have a preexisting neuropathological diathesis to develop parkinsonism (Jabs et al. 2003). Familial factors (e.g., genetic traits) were implicated in a recent study showing that patients whose first-degree relatives had movement disorders were more likely to demonstrate EPS (including NIP) when treated with antipsychotics than patients without this family history (Lencer et al. 2004).

Positron emission tomography (PET) and other technologies have been utilized to examine the relationship between D 2 receptor blockade in the basal ganglia and both antipsychotic efficacy and NIP. Of note are findings that with conventional agents at least 60% occupancy of D 2 receptors is needed for satisfactory antipsychotic response but that NIP tends to occur with ≥80% occupancy (Farde et al. 1992). Interestingly, some clinicians using conventional antipsychotics expected efficacy at the dose where patients exhibited mild parkinsonism, such that causing mild EPS was considered by some to be a treatment goal.

With regard to atypical agents, there are several hypotheses about their decreased incidence of EPS, including NIP, compared to typical agents (Casey 2004). Most atypical antipsychotics have a high ratio of serotonin type 2 (5HT 2A , 5HT 2C ) -to- D 2 receptor blockade. Serotonin receptor blockade may have antipsychotic effects that are synergistic with D 2 blockade, allowing for therapeutic effects at relatively lower levels of D 2 blockade. Also, there are 5HT 2A and 5HT 2C receptors on striatal dopamine neurons, and their blockade appears to
NIP . Similar to conventional antipsychotics, higher doses of
and there are likely multiple pathways to increase or decrease
ics categorized as “atypical,” these ideas remain speculative,
dopamine receptors more so than striatal receptors. Given the
that atypical drugs may have a relative specifi city for limbic
pensity for EPS. Neurobiological studies have also indicated
they block than typical drugs, and that this decreases pro-
atypicals exhibit more rapid dissociation from the receptors
promote dopamine release. Others have proposed that many
some atypical agents (particularly risperidone) also appear to
be related to an increase in NIP, as D2 receptor blockade may
increase with the dose of the atypical drug (Glazer 2000).

Epidemiology and Comorbidity
The reported frequency of NIP varies from 5 to 90%,
depending on the study reviewed (Lohr and Jeste 1988a).
This wide variation is due in part to inter-study differences
in defining NIP (e.g., the inclusion of mild bradykinesia as
NIP in some investigations). The incidence of “clinically
significant” NIP with conventional antipsychotics has been
reported as 10 to 15%. However, when high-potency
conventional agents are used without anticholinergic drugs
and signs of rigidity are carefully assessed, one is likely to
find that the majority of patients have some NIP. Rates of
parkinsonism induced by atypical antipsychotics are consider-
ably lower (American Psychiatric Association 2000). The
incidence of NIP appears age-related, with older adults at
increased risk. A study of newly medicated older patients
on low doses of conventional antipsychotics found 32% of
patients met criteria for NIP (Caligiuri et al. 1999).

A number of other patient-related and medication-
related risk factors have been proposed. A history of prior
episodes of NIP and concomitant dementia or delirium may
predispose to NIP (American Psychiatric Association 2000).
In an investigation of EPS in patients with Alzheimer dis-
ease treated with very low dose conventional antipsychotics,
67% of patients met criteria for NIP at some time during the
9-month follow-up period (Caligiuri et al. 1998). Neurolep-
tic potency and pre-existing extrapyramidal symptoms may
also increase the risk of NIP (Chakos et al. 1992). Rapid
increases in antipsychotic dosage, administration of higher
absolute doses of antipsychotics, and absence of concurrent
anticholinergic medication represent other risk factors for
NIP (American Psychiatric Association 2000).

Assessment and Differential Diagnosis
NIP symptoms may develop quickly after the initiation of
an antipsychotic or insidiously during the course of treat-
ment, with a typical onset being 2 to 4 weeks after antipsy-
chotic initiation. The three cardinal symptoms of NIP are
tremor, muscle rigidity, and akinesia.

Parkinsonian tremor is a steady, rhythmical, oscilla-
tory motion generally at a frequency of 3–6 Hz. The most
affected body area tends to be the upper extremities, but
the tremor may spread to the head, neck, jaw, face, tongue,
legs, and trunk. The tremor is typically most prominent at
rest, suppressed during action, and increased during times
of anxiety, stress, or fatigue (American Psychiatric Associa-
tion 2000).

Parkinsonian muscle rigidity appears clinically as a firm-
ness and spasm of muscles at rest that may affect all skeletal
muscles or be confined to just a few specific muscle groups.
It can appear as a continuous lead pipe-type rigidity that
resists movement or a cogwheel-type rigidity that presents
a “ratchet-like” resistance when a muscle is moved around
a joint. The psychiatrist may diagnose cogwheel rigidity by
placing his or her hand over the joint that is being passively
moved (e.g., during forearm pronation/supination or wrist
flexion/extension). Generalized muscle pain, body aches,
and impaired coordination are features associated with NIP
rigidity (American Psychiatric Association 2000).
Parkinsonian bradykinesia (or, if severe, akinesia) clinically manifests as decreased spontaneous motor activity and a global slowness in the initiation and execution of movements. It can be associated with drooling, neck flexion, decreased blinking, stooped shoulders, and blank facial expression (“masked faces”) (American Psychiatric Association 2000). Formal tests of psychomotor speed (e.g., finger tapping) may be helpful in mild cases. Decreased arm swing during ambulation is often an early sign that may alert clinicians to NIP, and which patients themselves may fail to recognize. Objectively slowed movements may be accompanied by a subjective sense in patients that their mentation is slowed (bradyphrenia). Although not part of the parkinsonian “triad,” postural instability may accompany NIP and predispose affected patients to falls.

Parkinsonism occurs in numerous medical and neurological conditions and can be caused by many medications (e.g., calcium channel blockers, amoxapine) or toxins. Other psychotropics (e.g., antidepressants, anticonvulsants, and lithium) have been reported to cause parkinsonism, though at much lower rates than neuroleptics. Idiopathic PD should be considered in the differential diagnoses of NIP; Mena and de Yebedes (2006) recently highlighted some general differences between PD and NIP, including the following: (1) more symmetry of symptoms in NIP than PD; (2) poor response of symptoms to L-DOPA in NIP compared to PD; and (3) higher levels of the dopamine metabolite homovanillic acid (HVA) in spinal fluid of patients with NIP compared to PD.

The tremor of NIP must be distinguished from tremor caused by other conditions. In general, nonparkinsonian tremors are finer, faster, and worse on intention. Tremor associated with substance withdrawal typically presents with associated hyperreflexia and increased autonomic signs. Cerebellar-associated tremors are usually coarse, action tremors and may present with associated nystagmus, ataxia, or scanning speech. Strokes and other central nervous system (CNS) lesions that cause parkinsonism usually have associated focal neurological symptoms. NMS can present with akinesia and lead pipe-type rigidity but also has other associated findings, such as fever, elevated creatine kinase, and fluctuating consciousness (American Psychiatric Association 2000).

A number of primary psychiatric illnesses may mimic symptoms of NIP, including major depressive disorder, catatonia (from mood or psychotic disorders), negative symptoms of schizophrenia, and certain conversion disorders (American Psychiatric Association 2000). Often, the diagnosis of NIP should be made provisionally and clarified by a dosage reduction of antipsychotic or trial of anticholinergic medication (American Psychiatric Association 2000).

**Course**

NIP symptoms usually continue unchanged or diminish slowly in 2–3 months after onset. The signs and symptoms typically improve with a dose reduction, discontinuation of antipsychotic medication, or switch to an atypical antipsychotic in patients previously receiving a conventional antipsychotic. Improvement is also seen with the addition of antiparkinsonian medications. While typically reversible with medication discontinuation, NIP in a minority of patients (up to 20%) may persist or even progress in spite of drug discontinuation (Mena and de Yebedes 2006). Persistent NIP symptoms could occur when medications unmask latent parkinsonism in those with underlying diatheses. Alternatively, some studies have suggested that certain antipsychotics (e.g., haloperidol) may be neurotoxic to striatal dopamine neurons through decreasing neurotrophic factors and/or generating free radical damage (Mena and de Yebedes 2006).

**Treatment**

Many milder cases of NIP do not require treatment if they are not bothersome to the patient. A switch to an atypical agent should be strongly considered if troublesome NIP develops while on a conventional antipsychotic. Large randomized controlled trials have demonstrated reductions in parkinsonian symptoms in patients treated with atypical antipsychotics compared to typical drugs (Beasley et al. 1997, Chouinard et al. 1993). Clozapine and quetiapine may be particularly useful in patients prone to NIP, given their relative tolerability in the treatment of psychosis associated with idiopathic Parkinson’s disease (Miyasaki et al. 2006). If symptoms become troublesome, the initial step should be to decrease the dose of antipsychotic to the lowest effective dose for the patient. The next step is to add a low dosage of an anticholinergic medication. The equivalent of 2 mg/day of benztropine generally represents a reasonable starting point. Periodic attempts should be made to wean the patient from the anticholinergic agent. As many as 90% of patients do not require anticholinergic medication at the end of 3 months (Johnson 1978). Anticholinergic medication should always be tapered slowly to avoid the rapid redevelopment of parkinsonian symptoms as well as the possibility of uncomfortable cholinergic rebound symptoms. Anticholinergic medications may not be a viable choice in older patients due to risks of cognitive impairment, urinary retention, and constipation. Clinicians should also be mindful of reports of anticholinergic abuse (especially trihexyphenidyl) among persons with serious mental illness, who report a “high” from such medications (Buhrich et al. 2000).

Refractory cases of NIP do occur and may require more aggressive management. Increasing the dose of the anticholinergic medication is one possibility because some patients may require high doses to achieve relief from NIP. If such high doses are to be employed, they should be used for the shortest possible time, and rigorous attention should be paid to the possibility of untoward anticholinergic effects (i.e., delirium, urinary retention, fecal impaction). Consideration may be given to starting a dopaminergic agent, such as amantadine or perhaps even levodopa. A major concern with this treatment approach is the possibility of exacerbating the psychosis for which the antipsychotic medication is being prescribed. Trials of dopaminergic agents are therefore best attempted in an inpatient setting or with careful outpatient observation and assessment. A number of experimental treatment strategies have been proposed for the treatment of refractory cases including vitamin E, calcium supplementation, electroconvulsive therapy, dehydroepiandrosterone (DHEA), and l-deprenyl (Osser 1992, Nachshoni et al. 2005).

Another treatment approach for the refractory case is to further lower the dose of the antipsychotic medication or even discontinue it until the NIP resolves, and then resume a different antipsychotic at a low dose. This treatment strategy
may also need to be carried out in an inpatient setting to monitor early emergence of psychotic symptoms.

**Neuroleptic-Induced Acute Akathisia**

**Definition**
Neuroleptic-induced acute akathisia is defined as a subjective feeling of restlessness and an intensely unpleasant need to move occurring secondary to antipsychotic treatment. The Greek origin of the word indicates “inability to sit.”

**Etiology and Pathophysiology**
The pathophysiological mechanism of akathisia remains unknown. Investigators have offered a number of theories, including akathisia as a subjective response to the rigidity and akinesia of NIP, as a primary sensory disturbance with secondary motor effects, and as a reaction to dopamine blockade in the mesocortical system. Mesocortical dopaminergic neurons that innervate the prefrontal cortex seem to be resistant to depolarization induced by long-term antipsychotic treatment, suggesting a possible explanation for why akathisia often does not improve with time (Lohr and Jeste 1988a).

The possibility that excessive noradrenergic activity plays a role in the pathogenesis of akathisia is supported by the efficacy of beta-adrenergic blockers in improving some cases of akathisia. A model implicating noradrenergic pathways from the locus coeruleus to limbic structures in movement disorders such as akathisia has been postulated (Wilbur et al. 1988). The lower likelihood of akathisia with atypicals (Miller and Fleischhacker 2000) may also need to be carried out in an inpatient setting to monitor early emergence of psychotic symptoms. Note that high-potency conventional antipsychotics are less likely to cause akathisia than typicals, appreciable rates of akathisia are still reported with atypicals (Miller and Fleischhacker 2000). Clozapine-induced akathisia has ranged from 0% to 10% (Safferman et al. 1993) and a point prevalence of 13% was reported for risperidone (Miller et al. 1998). Akathisia may be a relatively common side effect of aripiprazole, which may be related to its relatively low rates of sedation and its partial agonist activity at dopamine receptors (Keck et al. 2006). Akathisia is thought by many psychiatrists to be a leading cause of nonadherence.

Higher doses of high-potency conventional antipsychotics appear to be more frequently associated with the appearance of akathisia (American Psychiatric Association 2000). Previous episodes of neuroleptic-induced akathisia increase the risk for future episodes if antipsychotics are restarted. Presence of NIP also appears to increase the risk of akathisia (Sachdev 2005a). As with other types of medication-induced movement disorders, structural brain disorders and mental retardation may also be risk factors (Sachdev 2005a).

**Epidemiology and Comorbidity**
Akathisia is a common side effect of antipsychotic treatment. It is estimated to occur in 20–75% of patients treated with conventional agents. The wide discrepancy in reported prevalence may result from a lack of consistency in the definition of akathisia, different prescribing practices, different study designs, and differences in population demographics (American Psychiatric Association 2000). While atypicals antipsychotics are less likely to cause akathisia than typicals, appreciable rates of akathisia are still reported with atypicals (Miller and Fleischhacker 2000). Clozapine-induced akathisia has ranged from 0% to 39% (Safferman et al. 1993) and a point prevalence of 13% was reported for risperidone (Miller et al. 1998). Akathisia may be a relatively common side effect of aripiprazole, which may be related to its relatively low rates of sedation and its partial agonist activity at dopamine receptors (Keck et al. 2006). Akathisia is thought by many psychiatrists to be a leading cause of nonadherence.

Higher doses of high-potency conventional antipsychotics appear to be more frequently associated with the appearance of akathisia (American Psychiatric Association 2000). Previous episodes of neuroleptic-induced akathisia increase the risk for future episodes if antipsychotics are restarted. Presence of NIP also appears to increase the risk of akathisia (Sachdev 2005a). As with other types of medication-induced movement disorders, structural brain disorders and mental retardation may also be risk factors (Sachdev 2005a).

**DSM-IV-TR Criteria**

**Neuroleptic-Induced Acute Akathisia**

**Definition**
Neuroleptic-induced acute akathisia is defined as a subjective feeling of restlessness and an intensely unpleasant need to move occurring secondary to antipsychotic treatment. The Greek origin of the word indicates “inability to sit.”

**Etiology and Pathophysiology**
The pathophysiological mechanism of akathisia remains unknown. Investigators have offered a number of theories, including akathisia as a subjective response to the rigidity and akinesia of NIP, as a primary sensory disturbance with secondary motor effects, and as a reaction to dopamine blockade in the mesocortical system. Mesocortical dopaminergic neurons that innervate the prefrontal cortex seem to be resistant to depolarization induced by long-term antipsychotic treatment, suggesting a possible explanation for why akathisia often does not improve with time (Lohr and Jeste 1988a).

The possibility that excessive noradrenergic activity plays a role in the pathogenesis of akathisia is supported by the efficacy of beta-adrenergic blockers in improving some cases of akathisia. A model implicating noradrenergic pathways from the locus coeruleus to limbic structures in movement disorders such as akathisia has been postulated (Wilbur et al. 1988). The lower likelihood of akathisia with atypicals (Miller and Fleischhacker 2000) may also need to be carried out in an inpatient setting to monitor early emergence of psychotic symptoms. Note that high-potency conventional antipsychotics are less likely to cause akathisia than typicals, appreciable rates of akathisia are still reported with atypicals (Miller and Fleischhacker 2000). Clozapine-induced akathisia has ranged from 0% to 10% (Safferman et al. 1993) and a point prevalence of 13% was reported for risperidone (Miller et al. 1998). Akathisia may be a relatively common side effect of aripiprazole, which may be related to its relatively low rates of sedation and its partial agonist activity at dopamine receptors (Keck et al. 2006). Akathisia is thought by many psychiatrists to be a leading cause of nonadherence.

Higher doses of high-potency conventional antipsychotics appear to be more frequently associated with the appearance of akathisia (American Psychiatric Association 2000). Previous episodes of neuroleptic-induced akathisia increase the risk for future episodes if antipsychotics are restarted. Presence of NIP also appears to increase the risk of akathisia (Sachdev 2005a). As with other types of medication-induced movement disorders, structural brain disorders and mental retardation may also be risk factors (Sachdev 2005a).

**Epidemiology and Comorbidity**
Akathisia is a common side effect of antipsychotic treatment. It is estimated to occur in 20–75% of patients treated with conventional agents. The wide discrepancy in reported prevalence may result from a lack of consistency in the definition of akathisia, different prescribing practices, different study designs, and differences in population demographics (American Psychiatric Association 2000). While atypicals antipsychotics are less likely to cause akathisia than typicals, appreciable rates of akathisia are still reported with atypicals (Miller and Fleischhacker 2000). Clozapine-induced akathisia has ranged from 0% to 39% (Safferman et al. 1993) and a point prevalence of 13% was reported for risperidone (Miller et al. 1998). Akathisia may be a relatively common side effect of aripiprazole, which may be related to its relatively low rates of sedation and its partial agonist activity at dopamine receptors (Keck et al. 2006). Akathisia is thought by many psychiatrists to be a leading cause of nonadherence.

Higher doses of high-potency conventional antipsychotics appear to be more frequently associated with the appearance of akathisia (American Psychiatric Association 2000). Previous episodes of neuroleptic-induced akathisia increase the risk for future episodes if antipsychotics are restarted. Presence of NIP also appears to increase the risk of akathisia (Sachdev 2005a). As with other types of medication-induced movement disorders, structural brain disorders and mental retardation may also be risk factors (Sachdev 2005a).

**Assessment and Differential Diagnosis**
Akathisia tends to occur within the first 4 weeks of initiating or increasing the dose of antipsychotic medication. It can develop rapidly after the initiation or the dose increase of an antipsychotic. Patients with akathisia tend to have subjective complaints of “inner restlessness,” most often in the legs. It may be difficult for the patients to describe their feelings. They feel that they must move, and this manifests as fidgeting, frequent changes in posture, crossing and uncrossing of the legs, rocking while sitting, marching in place, and shuffling when walking (American Psychiatric Association 2000). Some researchers have proposed subtypes of akathisia according to presence of objective, subjective, or both (mixed) symptoms (Sachdev 2005a), with mixed
presentations appearing most commonly and purely objective signs being relatively infrequent (Kim and Byun 2003).

Akathisia is often associated with dysphoria, anxiety, and irritability. When akathisia is severe, aggression or suicide attempts may result, although this causal link is controversial. Interestingly, akathisia has been proposed as a possible causal factor in the recently reported increase in “suicidality” associated with antidepressants in children, adolescents, and young adults (Muller-Oerlinghausen and Berghofer 1999). Akathisia in a psychotic patient can easily be mistaken for worsening of psychotic features, resulting in an increase in antipsychotic dose and an exacerbation of the akathisia.

The strange subjective discomfort associated with akathisia is the feature that seems to be most useful in making a differential diagnosis between neuroleptic-induced akathisia and other neuroleptic-induced movement disorders. TD is often associated with a lack of sensory perception of having a movement disorder. This contrasts with akathisia in which patients tend to be acutely aware of their distress. When patients with TD are uncomfortable, it is usually a result of social factors such as embarrassment and functional factors such as frustration over not being able to perform certain tasks. Another differentiating factor is that TD usually involves the face, mouth, and upper extremities, whereas akathisia more commonly involves the lower extremities. The rhythmical appearance of akathisia may sometimes suggest a tremorous condition. Thus, the tremor of NIP and idiopathic PD may be mistaken for akathisia, especially if the feet and legs are involved. Iron deficiency anemia can also present with symptoms similar to neuroleptic-induced akathisia. A number of other medications—particularly selective serotonin reuptake inhibitors—may produce akathisia clinically identical to that produced by antipsychotics (American Psychiatric Association 2000).

It is critical to differentiate akathisia from psychiatric disorders presenting with agitation, such as depression, mania, anxiety, schizophrenia, delirium, substance intoxication/withdrawal, and attention-deficit/hyperactivity disorder. Mistaking akathisia for a primary psychiatric disorder can result in an intervention that would be the exact opposite of what is appropriate (i.e., increasing the dose of an antipsychotic instead of decreasing it because akathisia is mistaken for worsening psychosis) (American Psychiatric Association 2000). Reports of “paradoxical worsening” with a neuroleptic should prompt consideration of akathisia as a side effect.

Akathisia symptoms also overlap with those of restless legs syndrome (RLS), although one study indicated less circadian variance and more “inner restlessness” with akathisia compared to RLS (Poewe and Hogl 2004). Interestingly, RLS is associated with dopamine abnormalities and responds to dopamine agonists (e.g., ropinirole). Both akathisia and RLS may occur in the course of idiopathic Parkinson’s disease or iron deficiency.

Course
Neuroleptic-induced akathisia typically lasts as long as antipsychotic treatment is continued but may have variable intensity over time (American Psychiatric Association 2000). Treatment of akathisia may or may not alter the course of the akathisia.

Treatment
Akathisia may be difficult to treat effectively. The best initial approach is to try and reduce the chance of developing akathisia by minimizing the dosage of antipsychotic medication. The use of atypical antipsychotics should be considered because of their lower risk of akathisia. If using conventional antipsychotics, a switch to a low-potency agent such as thioridazine or chlorpromazine may prove helpful because these antipsychotics seem to have somewhat lower propensity to cause akathisia than high-potency conventional antipsychotics. After these initial steps, consideration should be given to initiation of an anti-akathisic drug regimen. A number of agents have been reported to be effective, including beta-adrenergic blockers, anticholinergic drugs, benzodiazepines, and clonidine (American Psychiatric Association 2000).

When using additional medications to treat akathisia, the beta-blocker propranolol is often considered first-line treatment, given the relative strength of evidence for its efficacy (Adler et al. 1993). To maximize anti-akathisic effects, beta-blockers may need to be lipophilic so as to cross the blood–brain barrier and also may need to have activity at the beta-2 receptor—both of which are characteristics of propranolol (Miller and Fleischhacker 2000). Benzodiazepines such as clonazepam and lorazepam have been shown to be efficacious in the treatment of akathisia and are also a reasonable therapeutic option, especially when anxiety is a prominent clinical feature; however, their side effects and abuse potential should be considered. Anticholinergic agents such as benzotropine may also be tried, but less evidence exists to support their use. A limited number of studies have also shown possible roles for clonidine and amantadine in the treatment of akathisia (Miller and Fleischhacker 2000). Agents with 5HT 2A receptor blockade (e.g., mirtazapine, mianserin) have also been reported to be beneficial in akathisia. A small randomized, controlled trial found mirtazapine 15 mg/day and propranolol both improved akathisia more than placebo (Poyurovsky et al. 2006). Others have reported beneficial effects of vitamin B6 (600–1200 mg/day) in controlled trials (Miodownik et al. 2006).

PROPHYLACTIC ANTICHOLINERGIC MEDICATION: PROS AND CONS
One issue that remains controversial among researchers and psychiatrists is whether preventive anticholinergic medication should be given to patients who are starting antipsychotics. Arguments against this practice include the risk of anticholinergic side effects such as dry mouth, blurry vision, constipation, and urinary retention. Further, anticholinergic medication is associated with cognitive side effects, such as memory impairment, confusion, and delirium. Additionally, polypharmacy increases health care costs, and risk for treatment nonadherence often increases along with the regimen complexity. Although some researchers have suggested anticholinergics may increase TD risk, the relationship between anticholinergics and TD is not definitive (Jeste and Caligiuri 1993).

Arguments in favor of initiating prophylactic anticholinergic therapy point to the decrease in the frequency of EPS (including dystonias, akathisia, and akinesia) when anticholinergic drugs are prescribed prophylactically (Winslow et al. 1986). Furthermore, medication nonadherence and
decompensation may relate to inadequately treated EPS, especially akathisia and akinesia (Rifkin et al. 1975, Diaz et al. 2004). With the introduction and increased use of atypical antipsychotics, the risk of EPS has decreased, thus reducing the need for prophylactic anticholinergic medication for many patients prescribed atypical agents.

Although this complicated issue remains unresolved, some basic guidelines can be proposed. When high-potency conventional antipsychotics are prescribed for young to middle-aged adults, antipsychotic and anticholinergic medications may be administered concurrently, with the anticholinergic medication tapered slowly within the next few weeks. When psychosis is mild and antipsychotic medication may be gradually increased, it may be best to avoid anticholinergic medications until such time as they become clinically necessary. In patients with pre-existing cognitive impairment or those at high risk for developing such (e.g., older adults), anticholinergic medications are best avoided if possible. In general, long-term prophylactic use of anticholinergic medication is not recommended (Ungvari et al. 1999).

A summary of the treatment of acute neuroleptic-induced movement disorders is provided in Table 84–2.

### Etiology and Pathophysiology

Historically, striatal dopamine receptor supersensitivity (as a compensatory reaction to prolonged dopamine receptor blockade) has been the most prominent theory regarding the etiology of TD. Evidence in favor of this hypothesis includes increased striatal D2 receptor binding using positron emission tomography among TD patients (Margoolese et al. 2005). Yet, the D2 supersensitivity seen in animal models of TD develops rapidly and almost invariably, whereas the clinical features of TD occur more slowly and only in a subset of patients (Jeste and Wyatt 1982, 2005a). It now seems more likely that a number of separate neurotransmitter systems are involved in the pathogenesis of TD. Some animal data implicate damage to gamma-aminobutyric acid (GABA)-containing striatal neurons as a causative factor in TD. There is also evidence that degeneration of striatal cholinergic interneurons and the resulting dopamine-aceytcholine imbalance play a role in TD pathogenesis (Jeste et al. 1992, Margoolese et al. 2005). Lohr and Jeste (1988b) suggested that long-term antipsychotic use may produce toxic free radicals that damage striatal neurons and result in persistent TD. Antipsychotics may increase dopamine turnover, elevating levels of hydrogen peroxide and consequently free radicals, and antipsychotics may also generate free radicals via inhibition of the mitochondrial respiratory chain (Margoolese et al. 2005). Other abnormalities reported to be associated with TD include reduced levels of brain-derived neurotrophic factor (BDNF) and elevated serum homocysteine (Lerner et al. 2005, Tan et al. 2005). Additionally, several candidate genes for increasing TD risk have been reported (e.g., serotonin receptors, dopamine receptors, cytochrome P450 enzymes) though none of these results are conclusive (Fernandez et al. 2003).

### Epidemiology and Comorbidity

The reported prevalence of TD has varied as a result of differences in study methodology (e.g., populations sampled, TD definitions, assessment measures) (Jeste and Wyatt 1981). Yassa and Jeste (1992) reviewed 76 studies of the prevalence of TD published from 1960 to 1990. In a total population of approximately 40,000 patients, the overall prevalence of
TD was 24.2%, although it was much higher (about 50%) in studies of elderly patients treated with antipsychotics. Children may also be at increased risk for the development of TD with antipsychotic treatment (Nasrallah 2006).

There have been relatively few studies of the incidence of TD. Kane and coworkers (1988) prospectively studied more than 850 patients (mean age 29 years) and found the incidence of TD after cumulative exposure to conventional antipsychotics to be 5% after 1 year, 18.5% after 4 years, and 40% after 8 years. Incidence in older populations has been found to be much higher. In fact, aging appears to be an important and consistent risk factor for the development of TD. The reasons for this increased risk of TD with aging are not known but may be related to the propensity of the nigrostriatal system to degenerate with age as well as pharmacokinetic and pharmacodynamic factors (Jeste and Caligiuri 1993). Jeste and coworkers (1995) evaluated 439 psychiatric patients with a mean age of 65 years and found that 28.8% of the sample met criteria for TD during the first 12 months of study treatment; 50.1% had TD by the end of 24 months, and 63.1% by the end of 36 months. The risk of severe TD has also been reported to be higher in older patients (Caligiuri et al. 1997).

Evidence supporting a reduced risk of TD with atypical antipsychotics is beginning to emerge. Although precise long-term rates remain unknown, preliminary 1-year incidence rates of TD with atypical antipsychotics have ranged from 0.4 to 2.6% (compared to 3–5% with typical agents) (Nasrallah 2006). The lower risk of EPS with atypical agents has led to the widespread opinion that these agents will also have reduced TD risk. The low risk of TD in clozapine-treated individuals has been well established (Lieberman et al. 1991). In addition, a lower incidence of TD has been reported in patients treated with risperidone (Chouinard et al. 1993, Jeste et al. 1999) and olanzapine (Tollefson et al. 1997). Another trial yielded significantly less TD with quetiapine compared to haloperidol (Emsley et al. 2004). In two studies comparing the rate of TD with typical vs. atypical antipsychotics in older adults, Jeste et al. (1999) and Dolder and Jeste (2003) found that the rate with atypical agents over 6–9 months was about 5 times lower than that with typical neuroleptics. Additionally, Jeste et al. (2000) reported that the one-year incidence of persistent TD with risperidone in elderly patients with dementia was less than 2%.

Gender (female) was thought to be a risk factor for TD. A meta-analysis of the published reports demonstrated a greater prevalence of TD in women (26.6%) compared with that in men (21.6%) (Yassa and Jeste 1992). Interestingly, studies of incidence of TD in older patients failed to confirm the reported propensity of women to have TD at a higher rate than men (Jeste et al. 1995). A possible interaction between gender, age of onset of schizophrenia, and severity of dyskinesia has been reported as women with late-onset schizophrenia (LOS) and men with early-onset schizophrenia (EOS) had more severe dyskinesia than men with LOS and women with EOS (Lindamer et al. 2001).

There are conflicting reports regarding ethnicity as a risk factor for TD. In a study of 491 chronic psychiatric patients, no significant differences in TD prevalence were found among blacks, whites, and Hispanics (Sramek et al. 1991). Higher incidence rates of TD in African-Americans than in whites, however, have been reported (Morgenstern and Glazer 1993). Wonodi et al. (2004) found less improvement among African-American patients with established TD than among comparable Caucasian patients. Aside from genetic factors, possible explanations for higher rates of TD among African-Americans compared to whites include use of higher doses, a higher prevalence of slow metabolizers, and a high rate of misdiagnosis of mood disorders among African-Americans (Nasrallah 2006). There is some evidence that Asian patients may have the lowest prevalence rate of TD (Leung et al. 2003).

Total exposure to typical antipsychotic agents has been correlated with TD risk (Casey 1997) and, within elderly populations, cumulative amount of typical antipsychotics has also been associated with TD risk, especially with high-potency conventional agents (Jeste et al. 1995).

**Neuroleptic-Induced Tardive Dyskinesia**

A. Involuntary movements of the tongue, jaw, trunk, or extremities have developed in association with the use of neuroleptic medication.

B. The involuntary movements are present over a period of at least 4 weeks and occur in any of the following patterns:

- (1) choreiform movements (i.e., rapid, jerky, nonrepetitive)
- (2) athetoid movements (i.e., slow, sinuous, continual)
- (3) rhythmic movements (i.e., stereotypies)

C. The signs or symptoms in criteria A and B develop during exposure to a neuroleptic medication or within 4 weeks of withdrawal from an oral (or within 8 weeks of withdrawal from a depot) neuroleptic medication.

D. There has been exposure to neuroleptic medication for at least 3 months (1 month if age 60 years or older).

E. The symptoms are not due to a neurological or general medical condition (e.g., Huntington’s disease, Sydenham’s chorea, spontaneous dyskinesia, hyperthyroidism, Wilson’s disease), ill-fitting dentures, or exposure to other medications that cause acute reversible dyskinesia (e.g., L-dopa, bromocriptine). Evidence that the symptoms are due to one of these etiologies might include the following: the symptoms precede the exposure to the neuroleptic medication or unexplained focal neurological signs are present.

F. The symptoms are not better accounted for by a neuroleptic-induced acute movement disorder (e.g., neuroleptic-induced acute dystonia, neuroleptic-induced acute akathisia).

The observation that anticholinergic drugs exacerbate some symptoms of TD does not appear to indicate that the drugs promote the onset of the disorder (Jeste and Caligiuri 1993).

A wide variety of other TD risk factors have been investigated. People with diabetes mellitus may be at a higher risk for development of TD as well as spontaneous dyskinesias (Woerner et al. 1993). Caligiuri and Jeste (2004) demonstrated more prevalent and more severe TD among older adults with versus without diabetes mellitus, particularly among those taking atypical antipsychotics. The presence of dementia or delirium may or may not be a risk factor for TD. Mood disorders (especially unipolar depression) have been reported to increase risk for TD in a number of publications, although findings have been mixed (Casey 1988, Jeste et al. 1995). Yassa and coworkers (1984) determined central nervous system damage predisposed to TD, but other studies of older patients found organic diagnosis not to be associated with TD susceptibility (Jeste et al. 1995). Patients who experience an acute neuroleptic-induced movement disorder (especially parkinsonism or akathisia) are likely to be at a greater risk for development of TD if antipsychotic treatment is continued (Sachdev 2004). Other possible risk factors include negative symptoms, cognitive impairments, and comorbid substance abuse (Sachdev 2005a).

**Assessment and Differential Diagnosis**

TD may develop at any age and typically has an insidious onset. It may develop during exposure to antipsychotic medication or within 4 weeks of withdrawal from an oral antipsychotic (or within 8 weeks of withdrawal from a depot neuroleptic). There must be a history of at least 3 months of antipsychotic use (or 1 month in the elderly) before TD may be diagnosed (American Psychiatric Association 2000).

The most common features of TD are involuntary movements of the tongue, face, and neck muscles. Less common are movements in the upper and lower extremities as well as in the trunk. Most rare of all are involuntary movements of the muscle groups involved with breathing and swallowing. The earliest symptoms typically involve buccolingual–masticatory movements. The movements of TD are choreiform (rapid, jerky), athetoid (slow, sinuous), or rhythmic (stereotypical) (American Psychiatric Association 2000).

Severe choreoathetoid dyskinesia differs from the milder forms mainly in the frequency and amplitude of the abnormal movements. Some cases of severe dyskinesia consist of generalized choreoathetosis of the face, trunk, and all four limbs (Casey and Rabins 1978). TD may be accompanied by dystonias, parkinsonism, and akathisia (Bitton and Melamed 1984).

TD is worsened by psychostimulants, short-term withdrawal of antipsychotic medication, anticholinergic medication, emotional arousal, stress, and voluntary movements of other parts of the body. It is improved by relaxation, voluntary movements of the involved parts of the body, sleep, and increased dose of antipsychotics (temporarily).

The differential diagnosis of TD is extensive. A number of nondyskinetic movement disorders are part of the differential diagnosis of TD. Tremor can be confused with TD, including the tremor of neuroleptic-induced parkinsonism, rabbit syndrome, Wilson’s disease, and cerebellar disease. Furthermore, fine tremors of the fingers and hands are produced by anxiety states, alcoholism, hyperthyroidism, and drugs. Acute dystonias, myoclonus, tics, mannerisms, compulsions, and akathisia must be differentiated from TD. The differentiation is made on the basis of the clinical assessment. For further details, the reader is referred to Jeste and Wyatt (1982).

Once it has been established that the patient suffers from a dyskinesia, the main cause must be determined; a number of conditions may cause dyskinesia besides antipsychotic treatment. Certain prescription medications may cause TD, including metoclopramide, antiemetics, and amoxapine. The use of antiparkinsonian medications such as levodopa, amantadine, and bromocriptine can cause dyskinetic movements. Sydenham’s chorea (a post-streptococcal complication) can produce choreiform movements in children. In the middle-aged or elderly patient, denture or dental problems may commonly mimic TD. Conversion disorder and malingering are conditions that can present with apparently involuntary movements. Hyperthyroidism and hypoparathyroidism are two endocrinological conditions that can produce dyskinesias similar to TD. Huntington’s disease is a condition that can be difficult to distinguish clinically from TD, but certain features suggest a diagnosis of Huntington’s disease, including (1) a family history of Huntington’s disease, (2) the presence of dementia, (3) a slowly progressive downhill course, and (4) atrophy of the caudate nucleus on computed tomography scan. Focal lesions of the basal ganglia (e.g., tumor, stroke) may also result in dyskinesias.

Interestingly, the original descriptions of dementia praecox by Kraepelin (well preceding antipsychotic use) include the following: “Several patients continually carried out peculiar sprawling, irregular, choreiform, outspreading movements...” (Friedman 2004). Subsequent reports have indicated an increased rate of dyskinesias in neuroleptic-naïve persons with schizophrenia, as well as in their first degree relatives (Friedman 2004, Honer et al. 2005). Spontaneous dyskinesias may also occur in association with aging. While some have argued that TD thus represents a manifestation of schizophrenia itself rather than pharmacotherapy, antipsychotics clearly increase the risk for dyskinesias above any baseline rate in schizophrenia.

When it has been established that antipsychotics are responsible for the dyskinesia, it does not follow that the dyskinesia is necessarily TD. Acute dyskinesia occurring early in antipsychotic treatment may occur and responds well to anticholinergic medications. Withdrawal–emergent dyskinesia also occurs in a variable proportion of patients. This phenomenon refers to the appearance or worsening of dyskinetic movements on reduction or discontinuation of antipsychotic medication. Withdrawal–emergent dyskinesia is phenomenologically similar to TD and often has the full range of involuntary choreiform and athetoid movements. A typical case may begin within a few days after a sudden decrease in dosage and worsen as the antipsychotic is withdrawn. This phase is followed by rapid improvement in a period of weeks to months. A history of antipsychotic exposure and remission of dyskinetic symptoms within 3 months of antipsychotic withdrawal are suggestive of the diagnosis of withdrawal–emergent dyskinesia (Gerhard 1992).

Finally, tardive tics must be differentiated from TD. A number of cases of “tardive Tourette’s disorder” have
been reported as a result of treatment with antipsychotics, emerging during treatment or after cessation of treatment (DeVauugh-Geiss 1980, Jeste and Wyatt 1982). Tardive tics present with symptoms similar to those of idiopathic Tourette’s disorder. Motor tics are usually compulsive organized stereotypies that may, in certain cases, be difficult to distinguish from the choreoathetoid movements of TD. Vocal utterances (including barks, grunts, coughs, and yelps) often represent tardive tics, though vocal phenomena may also occur in TD. Tardive tics seem to show a pharmacological response similar to that of TD (i.e., masked by an increase in antipsychotics and exacerbated by withdrawal), possibly indicating this syndrome is simply a variant of TD (Jeste et al. 1986).

Course
One-third of the TD patients experience remission within 3 months of discontinuation of antipsychotic medication, and approximately half have remission within 12 to 18 months of antipsychotic discontinuation (American Psychiatric Association 2000). Elderly patients are reported to have lower rates of remission, especially if antipsychotics are continued. When TD patients must be maintained with antipsychotics, TD seems to stabilize in 50%, worsen in 25%, and improve in 25%.

Time may be the most important factor in outcome of TD. In studies that have followed up patients for longer than 5 years, TD seems to improve in half of patients with or without antipsychotic treatment. Furthermore, TD may improve as slowly as it develops and may exist on a spectrum between resolution and persistence.

Severe TD may lead to numerous physical complications and psychosocial problems. Dental problems are common sequelae of severe oral dyskinesia, as are ulcerations of the tongue, cheeks, and lips (Yassa and Jones 1985). Hyperkinetic dysarthria and swallowing disorders have also been described in TD (Portnoy 1979). Respiratory disturbances, although fairly rare, have been reported by a number of investigators (Casey and Rabins 1978, Weiner et al. 1978). These disturbances are usually manifested by shortness of breath at rest, irregularities in respiration, and various grunts, snorts, and gasps. Respiratory alkalosis may be seen on laboratory tests. Gastrointestinal complications of severe TD may involve vomiting and dysphagia secondary to disruption of the normal activity of the esophagus (Yassa and Jones 1985).

Emotional distress may accompany severe dyskinesia. Suicidal ideation may result from distress over the dyskinesia, and there have been reports of some successful suicides. General impairment of functioning may be related to the severity of the dyskinetic disorder. Social embarrassment as a result of TD may represent a reason that some patients with TD tend to be reluctant to leave their homes. Even mild dyskinesia may lead to anxiety, guilt, shame, and anger. These symptoms can lead to depressive episodes (Yassa and Jones 1985). Alternatively, mild dyskinesias may not be noticed or spontaneously reported by patients, making clinical vigilance for early signs of TD important.

Treatment
Despite intense effort, there is as yet no consistently reliable therapy for TD. As a result, the psychiatrist must focus primary efforts toward prevention of the disorder. Atypical antipsychotics appear to offer some advantage compared to older agents in terms of TD risk. Unnecessary antipsychotic use and excessive doses should be minimized. Patients with nonpsychotic mood or other disorders who need antipsychotics should receive the minimal necessary amounts of antipsychotic treatment and should have the medication tapered and then stopped once the clinical need is no longer present. In general, there must be enough clinical evidence to show that the benefits outweigh the potential risks of TD development. Antipsychotics should be used with particular caution in elderly patients because of their high risk for development of TD (Figure 84–1).

Gradual taper of the antipsychotic medication may be attempted as long as the risk/benefit ratio of antipsychotic maintenance versus withdrawal does not preclude such a

---

Figure 84–1 Management of tardive dyskinesia (TD).
strategy. Using the lowest effective antipsychotic dose for long-term treatment of schizophrenia may help reduce TD risk. Paradoxically, antipsychotics themselves represent the most effective short-term treatment for TD. An increase in dosage of a conventional agent usually (in approximately 66% of patients) results in a clinically significant but temporary reduction in TD symptoms (Jeste et al. 1988). Atypical antipsychotics offer a means for reducing TD risk from treatment inception, though this advantage should be discussed with patients in the context of other possible side effects of atypical medications (e.g., metabolic effects). Clozapine may be effective in reducing TD in patients with existing TD (Lieberman et al. 1991, Small et al. 1987); however, side effects such as agranulocytosis, seizures, and anticholinergic symptoms limit its use. Additional studies have noted a beneficial effect of other atypical agents (i.e., risperidone and olanzapine) on preexisting TD (Jeste et al. 1997, Littrell et al. 1998). While some have argued that this could be a masking effect of atypicals on TD symptoms, Kinon et al. (2004) found open-label olanzapine reduced preexisting TD, and there was no rebound worsening in a blinded dose reduction phase.

A number of experimental studies have attempted to treat TD with alternative strategies. Jeste and coworkers (1988) reviewed these treatments and noted that they had variable and inconsistent degrees of success. One treatment that has demonstrated some efficacy is vitamin E (alpha-tocopherol). Lohr and Jeste (1988b) have proposed that antipsychotic treatment results in the production of free radicals that damage neurons. An antioxidant such as vitamin E might therefore, theoretically, result in improvement in the symptoms of TD. Zhang et al. (2004) found open-label olanzapine reduced preexisting TD, and a double-blind, placebo-controlled multicenter trial failed to show a difference between vitamin E and placebo after 1 year of treatment (Adler et al. 1998); however, a double-blind, placebo-controlled multicenter trial failed to show a difference between vitamin E and placebo after 1 year of treatment (Adler et al. 1999). The results are far from conclusive, but vitamin E has been used by some clinicians to treat TD because of its perceived benign nature. Yet, a recent meta-analysis demonstrating a slight increased risk of mortality with high dose vitamin E (largely in nonpsychiatric populations) compared to placebo makes the risk–benefit of this treatment in TD more difficult to interpret (Miller et al. 2005). Other previously mentioned theories of TD pathophysiology (e.g., damage to GABA and acetylcholine neurons) have led to other experimental treatments for TD, including benzodiazepines and cholinomimetics, but with inconsistent results. A recent small controlled trial of branched-chain amino acids led to improvement in TD compared to placebo, perhaps due to inhibition of CNS uptake of aromatic amino acid precursors of monoamines (Richardson et al. 2007). Damier and coworkers (2007) recently reported promising benefits of deep brain stimulation of the globus pallidus for recalcitrant TD.

Psychiatrists should regularly (e.g., every 3–6 months) assess for the presence and/or progression of TD and present the patient (or the patient’s guardian) with information about the risks of treatment. The Abnormal Involuntary Movement Scale (AIMS) is a quick and common means for doing so (Farr et al. 1977). Psychiatrists may also give written information sheets, assess understanding by the patient or guardian, and accurately record evidence of the informed consent in the patient’s record.

Other Tardive Movement Disorders

Dyskinesia is not the only late-onset neuroleptic induced movement disorder. Tardive tics were discussed above in the differential diagnosis of TD. Other examples include tardive dystonia, tardive tremor, tardive myoclonus, and tardive akathisia. These are all less clearly characterized and less common than TD, and affected patients often also have TD. Tardive dystonia, like acute dystonia, may occur more often in young adults and males, and may respond to anticholinergics. Botulinum toxin may represent a treatment option for severe or persistent tardive dystonia (Brashear et al. 1998).

OTHER NEUROLEPTIC-INDUCED DISORDERS

Neuroleptic Malignant Syndrome

Definition

Neuroleptic Malignant Syndrome (NMS) is a potentially fatal reaction to antipsychotic medications that is characterized clinically by muscle rigidity, fever, autonomic instability, and altered level of consciousness.

DSM-IV-TR Criteria

**Neuroleptic Malignant Syndrome**

A. The development of severe muscle rigidity and elevated temperature associated with the use of neuroleptic medication.

B. Two (or more) of the following:

1. diaphoresis
2. dysphagia
3. tremor
4. incontinence
5. changes in level of consciousness ranging from confusion to coma
6. mutism
7. tachycardia
8. elevated or labile blood pressure
9. leukocytosis
10. laboratory evidence of muscle injury (e.g., elevated CPK [creatine kinase])

C. The symptoms in criteria A and B are not due to another substance (e.g., phencyclidine) or a neurological or other general medical condition (e.g., viral encephalitis).

D. The symptoms in criteria A and B are not better accounted for by a mental disorder (e.g., mood disorder with catatonic features).

Etiology and Pathophysiology

The pathophysiological mechanism of NMS remains unclear. The hypothesis of most interest is that of reduced dopaminergic activity secondary to neuroleptic-induced dopamine blockade. This reduced dopamine activity in different parts of the brain (hypothalamus, nigrostriatal system, and corticolimbic tracts) may serve to explain the various clinical features of NMS. Dopamine reduction in the hypothalamus may cause fever and autonomic instability; in the nigrostriatal system, dopamine reduction may lead to the rigidity; and the reduction in corticolimbic dopamine activity may explain the altered consciousness (Sewell and Jeste 1992). This hypothesis is based on the fact that antipsychotics are dopamine-blocking agents, whereas certain dopamine agonists are reported to help resolve NMS.

The dopaminergic blocking theory does not, however, explain why NMS may develop at a given time and in a given patient. There are probably other genetic, constitutional, environmental, and pharmacological factors that interact to produce the syndrome. Candidate genes identified as NMS risk factors in small studies include the D2 receptor, 5HT2A receptor, cytochrome P450 2D6, and the ryanodine receptor (involved in calcium regulation in muscles) (Kawanishi 2003). A number of investigators have proposed that other neurotransmitter abnormalities may be responsible for the syndrome, including serotonin, norepinephrine, and GABA changes. Gmitter (1999) proposed a comprehensive model in which sympathetic nervous system (SNS) dysregulation was posited to be the central mechanism of NMS, caused by neuroleptics’ interruption of higher cortical tonic inhibition of the SNS (i.e., with resultant SNS hyperactivity).

Epidemiology and Comorbidity

The exact frequency of NMS is unknown. A number of retrospective and prospective studies have found 0.02 to 3.2% of patients treated with antipsychotics to be affected with NMS. Several factors probably account for this large variability in frequency, including differences in study methods and diagnostic criteria for NMS (Adityanjee et al. 1999, Sewell and Jeste 1992).

A number of retrospective studies have attempted to isolate possible risk factors for the development of NMS. A prior episode of NMS appears to predispose to future episodes of NMS. Rosebush and coworkers (1989) found that the risk of recurrent NMS decreased as the time from an original NMS episode increased.

Preexisting medical problems, especially those associated with agitation or dehydration, may predispose neuroleptic-treated patients to develop NMS. Patients with a neurological condition and those with human immunodeficiency virus (HIV) may be at higher risk for development of NMS (Shalev et al. 1989). A number of potential risk factors related to antipsychotic treatment have been identified. Higher doses of antipsychotic, rapid increases in dosage (e.g., “rapid neuroleptization”), and intramuscular injections of high-potency conventional agents (e.g., haloperidol and fluphenazine) have been reported as risk factors for NMS (Keck et al. 1989). Coadministration of lithium with an antipsychotic has been proposed as a risk factor for NMS development, but the data regarding this are contradictory (Sewell and Jeste 1992). NMS has been reported with all of the atypical antipsychotics (including clozapine), and a recent review of atypical-induced NMS concluded that symptoms appear similar to NMS induced by conventional antipsychotics, though there was an inconclusive observation of lower mortality in NMS induced by atypicals compared to typicals (Ananth et al. 2004).

NMS is more frequently reported in men than in women and appears associated with younger age. A previous diagnosis of a mood disorder may place patients at a higher risk for NMS. Warm, humid climates may also predispose to the disorder (American Psychiatric Association 2000).

Assessment and Differential Diagnosis

NMS usually presents in the first month of antipsychotic treatment but may develop at any time. Two-thirds of the cases manifest within the first week of treatment (American Psychiatric Association 2000). The two key diagnostic features for the disorder are severe muscle rigidity (classically referred to as lead pipe rigidity) and fever. A number of other features are also seen (see DSM-IV-TR criteria). For the psychiatrist, the most suggestive features are fluctuating consciousness (from confusion to coma), labile vital signs (tachycardia, unstable or elevated blood pressure), laboratory evidence of muscle injury (elevation of creatine kinase), and leukocytosis. Other features include diaphoresis, dysphagia, tremor, incontinence, and mutism (American Psychiatric Association 2000). The DSM-IV-TR criteria are broader than earlier criteria proposed by Pope and coworkers (1986), which require the following three items for a definite diagnosis: (1) oral temperature of at least 38°C in the absence of another known cause; (2) at least two extrapyramidal side effects from the following list: lead pipe-type muscle rigidity, cogwheeling, sialorrhea, oscillographic crisis, retrocollis, opisthotonos, tremor, dysphagia, choreiform movements, dyskinetic movements, festinating gait, and flexor–extensor posturing; and (3) autonomic dysfunction characterized by two or more of the following: hypertension, tachycardia, tachypnea, prominent diaphoresis, and incontinence. Sachdev (2005b) recently published reliability and validity data for a 36-point NMS rating scale that assesses a variety of the associated symptoms.

The differential diagnosis of NMS can be difficult (Table 84–3). The most important point is that the psychiatrist must start by suspecting NMS and then carefully rule out other possible organic problems. Because medical illness is a likely predisposing factor, it is important to consider that NMS may be present even if a definitive organic disease is found to explain the NMS-like symptoms.

Numerous general medical and neurological conditions can present with symptoms that resemble NMS, including CNS infection, status epilepticus, subcortical brain lesions, porphyria, and tetanus (American Psychiatric Association 2000). The presence of significantly elevated temperature and severe muscle rigidity makes the diagnosis of NMS more likely.

The syndrome of lethal catatonia (seen in patients with uncontrolled manic excitement or catatonic schizophrenia) can mimic NMS (with increased temperature, autonomic irregularities, and elevated creatine kinase), and
Chapter 84 • Medication-Induced Movement Disorders

1787

the differential diagnosis can be difficult. It is obviously important to determine whether the patient is indeed being treated with an antipsychotic. Although NMS may clinically resemble catatonia, NMS does not typically have alternating periods of catatonic excitement and catatonic mutism. A past history of catatonic episodes is also important in making the differential diagnosis.

Heat stroke may also look like NMS but typically differs in that it presents with hypotension, dry skin, and limb flaccidity (American Psychiatric Association 2000). Malignant hyperthermia manifests similarly to NMS but generally occurs within the context of a patient’s receiving halogenated anesthetic agents or succinylcholine. This condition typically begins immediately after administration of the anesthetic agent in genetically susceptible individuals (American Psychiatric Association 2000).

Medications can cause a number of conditions that may present as syndromes similar to NMS. Allergic drug reactions may produce fever and autonomic instability but not rigidity (Peloner et al. 1998). Serotonin syndrome from serotoninergic medications (e.g., antidepressants, triptans for migraine) also presents with confusion, fever, rigidity, and autonomic dysregulation (Birmes et al. 2003). A medication history can help distinguish between the two syndromes, but many patients receive concomitant antipsychotics and serotoninergic antidepressants. Myoclonus, hyperreflexia, and diarrhea are more common in serotonin syndrome. Lithium intoxication and anticholinergic delirium can both resemble NMS, as can intoxication with amphetamines, cocaine, and phencyclidine. An NMS-like presentation has been described in Parkinson’s patients with rapid discontinuation of dopaminergic drugs (Hashimoto et al. 2003).

Course

The course of NMS is variable. Some cases may progress to death, whereas others may follow a mild self-limited course. Once the syndrome is recognized and the antipsychotic medication is discontinued, the syndrome usually resolves between 2 weeks and 1 month (American Psychiatric Association 2000).

Previous mortality rates were reported to be 4–25% (Sewell and Jeste 1992), though these appear to have declined in recent years to less than 10% with better recognition and treatment. The most common medical complications leading to morbidity and mortality are respiratory failure and renal failure. Shalev and coworkers (1989) reported that myoglobinemia and renal failure are the best predictors of mortality in NMS; the presence of either condition imparted a 50% mortality risk. In general, complications are a result of physiologic consequences of severe rigidity and immobilization such as deep vein thrombosis, pulmonary embolism, dehydration, and rhabdomyolysis (Peloner et al. 1998). A small number of NMS cases have been reported to suffer long-term neuropsychiatric sequelae, such as motor and cognitive impairments (Adityanjee et al. 2005).

Treatment

The most critical step in treatment (Table 84–4) is to recognize the clinical features of the syndrome and rapidly discontinue the antipsychotic. The importance of this initial step mandates that psychiatrists who use antipsychotics in their practice be cognizant of the early clinical features and recognize that the syndrome can occur at any time during the course of treatment. Shiloh et al. (2003) demonstrated that a protocol for monitoring motor, autonomic, and laboratory warning signs of NMS reduced the incidence to 0.2%, compared to 2.1% in treatment as usual.

Once NMS develops and the antipsychotic has been stopped, supportive care remains the core of treatment and often must be carried out in the context of a medical intensive care unit (Aranas and Rosenbaum 2000). Each supportive intervention should be targeted to a specific symptom. Examples of interventions include cooling blankets for fever, cardiac monitoring for arrhythmias, and parenteral hydration for dehydration. Monitoring for urine output and renal function is important, and hemodialysis has been reported to reverse acute renal failure associated with myoglobinuria in NMS (Sanai et al. 2006).

Some specific treatments for NMS have been proposed, but their beneficial effects are unclear. The muscle relaxant dantrolene is thought by some investigators to be helpful in decreasing rigidity, hyperthermia, and tachycardia. Dantrolene was first shown beneficial in malignant hyperthermia and appears to block release of calcium from muscle sarcoplasmic reticulum, possibly by interacting with the ryanodine receptor. The usually recommended dose is 1 to 3 mg/kg/day orally or intravenously in four divided doses (Aranas and Rosenbaum 2000). The dopamine agonist bromocriptine may also provide some relief of the symptoms, especially for muscle rigidity. Dosing is usually in the range of 5 to 10 mg orally three times a day (Aranas and Rosenbaum 2000). The two medications can be administered together; however, a study by Rosebush and coworkers (1991) not only cast doubt on the benefit of the use of these agents in the treatment of NMS but also pointed to the possibility that these agents actually retard the course of improvement of NMS. In this study, 8 of 20 patients with presumed NMS received dantrolene, bromocriptine, or both along with supportive care, and 12 of 20 received supportive care only. There was a suggestion that the resolution of the NMS episodes took longer in the patients treated with the additional medications. The treatments in the investigation were not randomized or controlled (i.e., more severe cases may have received the medications more frequently).

At present, the appropriate course is to begin with antipsychotic discontinuation and supportive care and to consider antidote therapy only if improvement in symptoms is not seen within the first few days. Caroff and Mann (1998) suggested that treatment of NMS should be individualized for each patient based on clinical signs and symptoms. For example, supportive care may be sufficient in mild and early cases of NMS. Trials of bromocriptine, dantrolene, or amantadine may be helpful for patients with moderate–severe symptoms. Anticholinergics are generally best avoided (they may impair heat dissipation in febrile patients). Benzodiazepines may be useful for agitation and rigidity in NMS. Electroconvulsive therapy (ECT) is another treatment option in NMS. ECT’s mechanism of action in alleviating NMS is unclear, though it does increase dopamine turnover in the brain. ECT is particularly useful when there is difficulty in distinguishing between NMS and lethal catatonia, when there is need for psychiatric treatment during a prolonged absence of antipsychotic pharmacotherapy, or when NMS symptoms are refractory. Some psychiatrists report rapid and dramatic success in use of electroconvulsive therapy for NMS.

A particular difficulty for the psychotic patient with NMS is that rechallenge with antipsychotics may cause NMS to recur. Successful rechallenge seems to be positively related to the length of time elapsed after resolution of NMS (Rosebush et al. 1989). Aside from avoiding the original offending agent, there are no absolute guidelines in choosing an alternative antipsychotic therapy after resolution of NMS in persistently psychotic patients. It is possible but not yet known definitively that atypical antipsychotics will prove to have a lower frequency of NMS. In general, it is recommended to switch to an agent in a different chemical class and with a lower D2 affinity compared to the causal agent (Peloner et al. 1998).

Medication-Induced Postural Tremor

Definition

This category refers to fine postural tremors that develop as a result of a medication. Medications that have been reported to cause such an effect are lithium, beta-adrenergic agonists, stimulants, dopaminergic medications, anticonvulsants, antipsychotics, antidepressants, and methylxanthines (e.g., caffeine) (American Psychiatric Association 2000). The psychotropic medication most typically associated with

</table>

such tremor is lithium, and most of the available information on medication-induced tremor relates to this drug.

**Etiology and Pathophysiology**

Normal muscle contractions are accompanied by a generally imperceptible tremor during muscle fiber recruitment. This tremor is typically low in amplitude and is referred to as a physiological tremor. When these contractions are maintained, the amplitude of the tremor increases and it becomes visible. This is referred to as an enhanced physiological tremor (Young 1992). A number of medications, including lithium and bronchodilators, produce an enhanced physiological tremor. The pathophysiologic mechanism of these tremors is not well understood but seems related to adrenergic-induced changes in the mechanical properties of the skeletal muscle (Young 1992). The response of these tremors to beta-adrenergic blocking agents and their exacerbation as a result of beta-adrenergic agonists lend support to the notion of adrenergic mediation.

**Epidemiology and Comorbidity**

Estimates of the frequency of lithium-induced tremor vary widely across the literature and range between 4 and 65%. Lifetime incidence of tremor is estimated to be 25–50% of patients on lithium therapy (Price and Heninger 1994). A number of risk factors for the development of lithium-induced tremors have been proposed. These include older age, greater serum lithium levels, concomitant use of antidepressant or antipsychotic medication, high caffeine intake, history of tremor, alcohol dependence, and anxiety (American Psychiatric Association 2000).

**Assessment and Differential Diagnosis**

Lithium-induced tremor may appear as soon as treatment is initiated. As the lithium level increases, the tremor becomes more severe and coarse and may have associated muscle twitching or fasciculations (American Psychiatric Association 2000). Complaints about the tremor are typically greatest at the beginning of therapy. There is disagreement as to whether the tremor typically remains stable or improves with time on lithium.

The lithium-induced tremor is reasonably easy to diagnose. It is a rhythmic tremor most prominent with sustained posture or movement. It commonly occurs in the hands or fingers but occasionally affects the head, mouth, or tongue (American Psychiatric Association 2000). The frequency of the tremor is typically 8–12 Hz and is similar in appearance to an essential tremor (Aran and Rosenbaum 2000). One can look for the tremor by asking the patient to hold the affected body part in a stable or outstretched position. The tremor is made worse by anxiety, stress, fatigue, hypoglycemia, thyrotoxicosis, pheochromocytoma, hypothermia, alcohol withdrawal, and performance of voluntary movements (American Psychiatric Association 2000, Arana and Rosenbaum 2000).

The most difficult differential diagnosis involves distinguishing a lithium-induced tremor from a preexisting tremor. To be classified as a medication-induced tremor, it must have a temporal relationship to the medication, it must relate to the serum level of the medication, and it must not persist after the medication is discontinued. A similar clinical condition is essential tremor, a common and sometimes familial illness, and differentiation between the two is nearly impossible clinically without the medication history.

Any of the factors listed that may exacerbate a medication-induced tremor can also cause a similar tremor in the absence of the medication. Medication-induced tremor may resemble NIP. NIP, however, is generally worse at rest, is lower in frequency, and has other associated features of parkinsonism (American Psychiatric Association 2000).

**Course**

Tremors may be embarrassing for patients and at times impair activities that require delicate movements (e.g., buttoning, clothing, drawing) (Arana and Rosenbaum 2000). The actual percentage of patients who are bothered by their tremor is unknown but likely substantial. There do not appear to be any long-term sequelae as a result of having a medication-induced postural tremor. A sudden worsening of tremor may be indicative of the beginning of lithium intoxication.

**Treatment**

Most treatment options have been described for treatment of lithium-induced tremor. Often the tremor is benign and not bothersome to the patient, in which case it requires no specific intervention. Patients with appreciable distress or functional impairment related to tremors, however, require treatment. Possible initial steps include reducing the lithium dose (if clinically feasible), changing to a one-time evening lithium dose, or changing the lithium preparation (e.g., to a sustained release formulation with possible reduced peak blood levels). Caffeine intake should be reduced or eliminated, and anxiety should be pharmacologically or behaviorally treated.

Beta-blockers represent the best-studied method for gaining pharmacological control of the tremor if the preliminary measures are ineffective. Arana and Rosenbaum

---

**DSM-IV-TR Criteria**

**Medication-Induced Postural Tremor**

A. A fine postural tremor that has developed in association with the use of a medication (e.g., lithium, antidepressant medication, valproic acid).

B. The tremor (i.e., a regular, rhythmic oscillation of the limbs, head, mouth, or tongue) has a frequency between 8 and 12 cycles per second.

C. The symptoms are not due to a preexisting nonpharmacologically induced tremor. Evidence that the symptoms are due to a preexisting tremor might include the following: the tremor was present prior to the introduction of the medication, the tremor does not correlate with serum levels of the medication, and the tremor persists after discontinuation of the medication.

D. The symptoms are not better accounted for by neuroleptic-induced parkinsonism.

Clinical Vignette 1: Tardive Movement Disorders

Mrs. L., a 59-year-old divorced woman, was diagnosed with paranoid schizophrenia at the age of 33, though her symptoms predated the clinical diagnosis by several years. Mrs. L. experienced intermittent paranoid delusions and command hallucinations for many years. After two hospitalizations and periods of treatment nonadherence, Mrs. L. began to accept her diagnosis. She responded well to treatment with oral fluphenazine, with marked reduction and eventual remission of positive psychotic symptoms. She had relatively few negative symptoms, but residual cognitive impairments impeded her occupational functioning. Due to periods of past nonadherence, her treating psychiatrist suggested she switch to the decanoate form of fluphenazine. She did so and remained on fluphenazine decanoate 25 mg every two weeks.

Around 2 years after starting treatment with fluphenazine, Mrs. L. developed orofacial dyskinesias consistent with TD. Over the subsequent 1–2 years, the dyskinesias in her orofacial muscles became somewhat more prominent and moderate in intensity. Also, she developed mild dyskinesias in her upper and lower extremities. Her truncal and respiratory muscles were never affected. Mrs. L. did not notice the dyskinesias initially and was never particularly bothered by them, even after her psychiatrist pointed them out to her, but she agreed that she did not want them to worsen. She discussed alternative treatments with her psychiatrist (e.g., oral low-potency antipsychotics, as atypical agents were not yet available), and decided to try lowering her fluphenazine dose by half. She soon experienced a temporary withdrawal-related increase in dyskinesias, which she found frightening (as she was not forewarned of this possibility), but which subsided. However, 4 months after lowering her fluphenazine dose she began to experience a relapse of hallucinations and paranoia. She and her treating psychiatrist decided to resume the original fluphenazine decanoate dose, with a short-term supplementation with oral fluphenazine. Her psychosis again resolved, and she did not wish to change treatments at that time despite the persistent dyskinesias.

Over the next several years, Mrs. L.’s TD symptoms waxed and waned but never disappeared or became significantly worse. Even with the advent of newer atypical agents, she preferred staying with a treatment which she knew had worked. At age 59, over the course of several weeks, Mrs. L. began to complain of a new symptom she had never experienced before, which she described as “nerves.” Upon further questioning, it was difficult for Mrs. L. to convey the feelings she was experiencing, but she felt that “anxious” and “restless” were the best fits to describe her symptoms. She was noted to be fidgeting and rocking in her seat and to be marching in place with her feet. She did not have a history of comorbid mood or anxiety disorder, denied new psychosocial stressors, and had not changed her medications recently. Tardive akathisia was felt to be the most likely diagnosis. A thorough discussion of treatment alternatives (including atypical antipsychotics) ensued, but Mrs. L. preferred to find a way to treat the akathisia symptoms and remain on fluphenazine if possible. She was being treated by a primary care physician for osteoarthritis and hypertension, and was receiving acetaminophen and amiodipine (a calcium channel blocker). In consultation with her primary care physician, amiodipine was switched to propranolol, titrated to 20 mg three times daily. Mrs. L. had a positive response to this change, with a significant reduction of her akathisia symptoms and good control of her blood pressure. Her TD symptoms remained largely unchanged, and she continued to have remission of psychosis with fluphenazine decanoate.

Clinical Vignette 2: Acute EPS/dystonia

Mr. J, a 23-year-old single man, was psychiatrically hospitalized after attacking his brother in response to paranoid delusions. He believed his brother had been replaced by an imposter. He had complained of stress to a primary care physician 4 months earlier, and he began treatment with paroxetine for “anxiety.” He noted some mild reduction in anxiety and thus continued to take the paroxetine. While in the emergency department prior to admission, the patient required emergent treatment for agitation and received haloperidol 5 mg intramuscularly. Upon his admission, the treating psychiatrist noted that he seemed tense primarily in reaction to paranoid beliefs, and the patient was started on risperidone 2 mg at bedtime. Mr. J later admitted to hearing the voice of a man commenting on his actions. The following morning Mr. J began to complain that his tongue “felt funny” and was told dry mouth could be a side effect of the medication. Two hours later, he began moaning loudly and pointing to his throat. His neck was noted to be forcefully rotated to the right and his speech was somewhat difficult to understand. His vital signs were normal and his breathing was not yet compromised. Emergent treatment with benzotropine 2 mg intramuscularly was ordered for a dystonic reaction. This resulted in partial relief of his torticollis and his speech improved, and the benzotropine dose was repeated 40 minutes later. Within 1 hour after the second dose, the dystonia had resolved completely, but the patient was still distressed by the events and even more suspicious. The treating psychiatrist felt paroxetine might have decreased metabolism of both haloperidol and risperidone via inhibition of cytochrome P450 2D6 and thus increased the risk of EPS. The psychiatrist explained this to the patient and they agreed to switch to another antipsychotic agent with less D2 receptor antagonism and with a different metabolic pathway, quetiapine. Prophylactic oral benzotropine was also continued for 1 week and then tapered slowly.

Comparison of DSM-IV/ICD-10 Diagnostic Criteria

Some of these categories are included in Chapter VI of ICD-10 (Diseases of the Nervous System) but no diagnostic criteria or definitions are provided.
Acknowledgements

The authors would like to recognize David Naimark and Chris Dolder for their outstanding contributions to the previous editions of this chapter. We also thank Sandy Kent for assistance in managing and formatting the references for the chapter.

Relational Problem Related to a Mental Disorder or General Medical Condition

Introduction
A relational problem is a situation in which two or more emotionally attached individuals (i.e., family members, romantic partners) engage in communication or behavior patterns that are destructive or unsatisfying, or both, to one or more of the individuals. Relational problems deserve clinical attention because, once initiated, they tend to be perpetuating and chronic, and are frequently contemporaneous with or followed by other serious problems, such as individual symptoms in the most vulnerable members of the family (e.g., depression) or social unit dissolution (e.g., divorce). They may be diagnosed either in the presence or absence of individual Diagnostic and Statistical Manual of Mental Disorders (DSM) disorders.

The strength and direction of causality between the individual and the relational problem are empirically undetermined. Few empirical investigations of the relational problems that are precursors to individual pathology have been conducted. Most of the existing research selects disturbed family units in which one member has an existing disorder (e.g., schizophrenia, depression) and examines the communication difficulties that accompany the disorder. Thus, cause-and-effect relations between individual disorders and relational difficulties often are not clearly specified. In some circumstances, individual psychopathology may lay the groundwork for relational difficulties, as when maternal depression disrupts the development of infant attachment processes (e.g., Cohn et al. 1986, Field et al. 2002, Larsen and O’Hara 2002). Relational difficulties also enhance the likelihood of the development of individual psychopathology, as when negative events in marriage increase the risk of depression in previously nondepressed individuals (Whisman et al. 2006). In some cases relational problems may interact with genetic vulnerabilities in contributing to the development of psychopathology (Wamboldt & Reiss 2006). For example, communication deviance in the adoptive parents of children at genetic risk for schizophrenia puts the child at greater risk for developing schizophrenia, when compared to children whose adoptive parents are low in communication deviance (Tienari and Wynne 1994).

There is also the issue of generalization: Do those who manifest relational problems with a spouse or other family member manifest these same problems with others and in other contexts? Some individuals manifest severe communication difficulties with their spouses or other family members but not with persons outside the family. However, relational problems in the marital dyad are strongly associated with parenting problems and parent–child conflict (Kitzmann 2000). Individuals in discordant intimate relationships display impairment in other social roles (Whisman and Uebelacker 2006). Thus, relational problems may generalize beyond the boundaries of the immediate relationship.

Definition
Relational problems are placed in the fourth edition of the DSM (DSM-IV-TR) section “Other Conditions That May Be a Focus of Clinical Attention.” There is debate on the most appropriate way to capture these clinical processes (First 2006). Five specific relational problems are described:
Relational problem related to a mental disorder or general medical condition: A pattern of impaired family interaction in the presence of a mental disorder or medical condition in a family member.

Parent–child relational problem: A pattern of family interaction between parent and child that shows signs of impairment, such as faulty communication, overprotection, or inadequate discipline. The family interaction is associated with clinically significant impairment or symptoms in an individual or in family functioning, or both.

Partner relational problem: A pattern of interaction between spouses or partners characterized by negative and distorted communication or noncommunication, which is associated with clinically significant impairment in one or both partners.

Sibling relational problem: A pattern of interaction between siblings that is associated with clinically significant impairment in individual or family functioning.

Relational problem not otherwise specified: Relational problems not listed here, such as extra-family relational problems or difficulties with others, such as coworkers.

Beach et al. (2006) make a distinction between relational disorders which could become the focus of clinical attention in the absence of other disorders (e.g., severe marital conflict) and relational risk factors, which would be unlikely to become the focus of clinical attention but may increase the risk of negative outcomes for an ongoing psychiatric disorder (e.g., high expressed emotion in relatives). We have included both in our review.

Constructs and Manifestations of Relational Problems

The empirical data substantiate the existence of relational difficulties that can be reliably assessed and have clinical significance (Beach et al. 2006, Clarkin and Miklowitz 1997). The data are sparse in reference to each DSM disorder and coexisting family relational difficulties, with the exceptions of depression, schizophrenia, and youth conduct disorders.

In our examination of the construct of relational problems, we emphasize those constructs that have shown reliable assessment in research and that have been found to (1) distinguish distressed from nondistressed couples or families or (2) identify couples or families in which one or more members manifest significant individual pathologic conditions. Some constructs with theoretical importance were found to lack one or both of these criteria and were not included in this review.

Four major constructs (Table 85–1) have been investigated that describe nodal areas of relational difficulty in the family and marital environment: structure, communication, expression of affect, and problem solving. Relational difficulties in other environments (e.g., work) have not been described in the clinical literature.

It is interesting to compare the constructs investigated in the couples and family contexts. The areas of affective communication and conflict resolution are almost identical in conceptualization, behavioral criteria, and importance in the spouse–spouse and parent–child communication domains. However, three other rather sharply defined constructs in the parent–child literature are not fully represented in the spouse–spouse literature: communication deviance (CD), emotional overinvolvement, and coercive process. In the cognitive realm, the CD construct (unclear, amorphous, or fragmented communication) has been investigated primarily among schizophrenic patients and their parents; comparable work has not been done with couples. The more general construct of communication has been explored with marital couples, with no theoretical link to thought disorder and schizophrenia.

Coercive processes—the shaping of the behavior of parents by negative behavior on the part of the child—is similar to negative escalation in couples. Although not yet investigated in couples, it is quite conceivable that one spouse could effectively engage in a coercive process with the other spouse. Overinvolvement, which has been explored in the parent–child literature may have a related domain in the marital literature—specifically, structure. The overinvolvement construct specifically has been seen as most relevant with children and parents and has little predictive utility in adult couple samples (Vaughn and Leff 1976a, Butzlaff and Hooley 1998, Hooley et al. 1986). However, it seems that the concept of structure, with the issues of leadership, dominance and submission, and distribution of functions, is an area that needs further exploration in reference to both couples and the entire family.

The Global Assessment of Relational Functioning Scale included in DSM-IV-TR for rating relational units utilizes the constructs that we have found in the empirical literature. The scale anchor points refer to structure (“agreed-on patterns or routines exist that help meet the usual needs of each family/couple member”), affect expression (“a range of feeling is expressed”; “despair and cynicism are pervasive”), communication (“communication is frequently inhibited”), and problem solving and conflict resolution (“decision making is usually competent”; “decision making is tyrannical or quite ineffective”; “unresolved conflicts often interfere with daily routines”). Descriptions and a review of the relevant research on each of these constructs—structure, communication, affect expression, and problem solving—will be reviewed below, both for couples and for families.

Structure

For a marriage or family to function as a unit requires leadership and distribution of functions. Leadership, dominance, and power distribution can all have a profound effect on the quality of interaction satisfaction and on adequate

functioning of both couples and families, both in ordinary and in stressful circumstances.

Couples
Power and dominance in relationships have been assessed in a variety of ways and sometimes appear related to relational functioning. For example, using measures of marital partners' influence patterns during discussion tasks, researchers have found that egalitarian couples (those in which couple solutions are equally reflective of each partner's ideas) have higher marital satisfaction than those with unequal power balances (Gray-Little et al. 1996). Power is also reflected in what has been termed the "demand–withdraw" pattern of communication in marriage. In this pattern, one partner makes demands, criticizes, or nags while the other partner withdraws, avoids conflicts, or becomes defensive. In this interaction pattern, the partner who makes demands is in a position of lesser power, as he/she is lobbying for change, while the partner in the "withdraw" position is in a position of greater power, as he/she can grant or deny change. A stable demand–withdraw pattern is frequently associated with relationship dissatisfaction (Eldridge and Christensen 2002). Although the wife-demand/husband-withdraw pattern appears to be more common, a husband-demand/wife-withdraw pattern may be apparent in severely violent couples (Babcock et al. 1993). In these couples, discussions may be characterized by blaming, defensiveness, criticism, and strong/early attempts at persuasion, suggesting intense conflicts over power (Gottman et al. 2003).

Power has been explored in couples with a depressed member. In these couples the power distribution is not always as theoretically hypothesized (i.e., depressed spouse submissive to dominance of the nondepressed partner). Contrary to expectation, Hooper et al. (1977) found that depressed patients produced substantial control-oriented communication with their spouses during an acute depressed episode. In a hospitalized sample, Merikangas et al. (1979) found that during early therapy sessions, the patient was strongly influenced by the behavior of his or her spouse; however, by the last session, there was a more equal balance of power. In contrast, introversion and interpersonal dependency may reflect enduring abnormalities in the functioning of individuals with remitted depression (Barnett and Gotlib 1988).

Families
Some parent–offspring relationships are marked by unclear boundaries and overdependence, often inhibiting the offspring's ability to separate, individuate, or recover from illness (Minuchin 1974). With respect to psychiatric and sometimes medical disorders, it is not unusual to see a pairing of an overprotective, overinvolved parent with a highly disabled, passive, withdrawn offspring. Because ill offspring in these families often elicit such responses, an overinvolved relationship generated by a parent. Overinvolvement is often difficult to define or assess in parents of school-age or adolescent children (Asarnow et al. 1987). However, among studies of youth, those focusing on separation anxiety, and school refusal in particular, describe parental overinvolvement and protective ness as complicating features (Kearney and Silverman 1995).

The term “expressed emotion” (EE) is used to refer to critical comments, hostility, and/or overinvolvement as expressed by a family member toward another family member with a mental disorder. EE studies and studies of family interaction have delineated other characteristics of overinvolved relationships in families of patients with schizophrenia. In terms of premorbid social adjustment, patients with schizophrenia in emotionally overinvolved families are more likely than those in normally involved families to have had poor premorbid social adjustment and a high level of residual symptoms after acute episodes (Miklowitz et al. 1983). Overinvolvement is reasonably common among families of patients with chronic schizophrenia (Miklowitz et al. 1986) but is infrequently observed among parents of recent-onset patients with schizophrenic disorder (Neuechterlein et al. 1986). Emotionally overinvolved parents of patients with schizophrenia are more likely than normally involved parents to use an excessive number of intrusive, “mind-reading” statements in direct family interaction (Miklowitz et al. 1984). They are also characterized by high levels of communication deviance (CD) (Miklowitz et al. 1986).

Several other studies suggest that parental overinvolvement combined with low levels of caring are retrospectively reported by patients with neurotic depression (Parker 1979, 1983) and borderline personality disorder (Zweig-Frank and Paris 1991). Interestingly, parental overinvolvement was associated with a better course of illness in one sample of individuals with borderline personality disorder (Hooley and Hoffman 1999). A study of adolescents at risk for psychosis found that parental overinvolvement predicted improvements in youths' negative symptoms and social functioning over a 3-month follow-up (O'Brien et al. 2006). Thus, the impact of overinvolvement varies across different forms of psychiatric disorder.

Communication of Information
Verbal communication between two or more individuals involves the various aspects of information exchange, including the amount and clarity of the information and the reception of the information by another. This broad concept of communication implies the willingness to convey information, the accuracy and clarity of the information, and the accurate decoding of the information by the other.

Couples
The amount and quality of verbal communication have differentiated distressed and nondistressed couples, and treatment leads to an improvement in communication (Ely et al. 1973). Measures of communication quality taken early in marriage are predictive of marital satisfaction four years later (Rogge and Bradbury 1999). In the area of information
exchange, there are more inaccuracies in the communication of distressed couples than in that of nondistressed couples owing to encoding (sending unclear messages) rather than decoding (understanding partner’s messages) errors. Distressed husbands were distinguished by more encoding and decoding errors than nondistressed husbands; (Noller 1981, 1984). Although both distressed and nondistressed couples are relatively inaccurate observers of their own interactional behavior, distressed couples are comparatively less reliable (Elwood and Jacobson 1982, 1988).

In addition to the overt verbal communication, various cognitive constructs are thought to be intimately related to the nature and quality of communication. Five areas of cognitive phenomena are hypothesized to play important roles in marital communication and maladjustment: selective attention, attributions, expectancies, assumptions, and standards (Baucom et al. 1989, Robinson and Price 1980). Not all of these areas have been equally investigated. First, distressed spouses focus on negative behavior; positive interactions often are ignored (Fincham and O’Leary 1983). Second, distressed spouses tend to attribute their partner’s undesired communicative behavior as global and stable (Camper et al. 1988, Holtzworth-Munroe and Jacobson 1985), and the partner is blamed for their or his negative behavior, which is seen as intentional, global, stable, and originating from internal factors. In contrast, nondistressed individuals give each other credit for positive behavior and overlook or exonerate their spouses for negative behavior (Jacobson et al. 1985, Fincham et al. 2000). While the stability or developmental history of these cognitive sets has not been clearly delineated, current evidence suggests that negative attributions for partner behavior may predict marital satisfaction over time (Karney and Bradbury 2000) and in addition to the impact of depression and/or low self-esteem (Fincham and Bradbury 2004). Third, the relationship between these attributions and marital satisfaction may be mediated by spouses’ efficacy expectations for the relationship (Markman 1981). In the area of expectations, Pretzer et al. (1991) found that spouses’ low efficacy expectations regarding their ability to solve their marital problems were associated with marital distress and depression. Data on premarital communication patterns and later marital conflict also suggest that certain forms of premarital communication (as opposed to specific content areas) predict a growing negative cognitive set held by partners toward each other (Buehman et al. 1992). Indeed, among both newlywed couples and couples with young children, spouses’ cognitions about the relationship were highly predictive of divorce or stability over time (Carrere et al. 2000, Epstein and Eidelson et al. 1981). Fourth, in the area of distorted assumptions that can affect marital behavior, it has been found that distressed spouses make the assumption that their partners cannot change the relationship and that overt disagreement is destructive (Jordan and McCormick 1987). Fifth, and relatedly, unrealistic assumptions and standards about relationships are predictive of general marital distress (Patterson 1982, Patterson et al. 1991).

Families

Many of the same disordered processes (e.g., expression of hostility or excessive criticism, poor information exchange, lack of conflict resolution) in the spousal communication literature are presumed to disrupt healthy family functioning. Unlike in the marital literature, however, the independent variable in family studies is often the presence or absence of a psychopathologic condition in an offspring or parent rather than high or low levels of marital distress. In this section, we review disordered processes within families that have empirical validity in distinguishing disordered from non-disordered states, including coercive family processes and communication deviance.

Coercive Communication Processes

When two individuals within a family (i.e., a parent and child) are controlling each other’s behavior via aversive stimuli or responses that are perceived by these individuals or by others in the family as unpleasant, a “coercive entrapment” has developed (Patterson 1982). The key ingredient to such entrapment is negative reinforcement. In this model, children first learn to perform mild, relatively innocuous aversive behaviors (e.g., whining, teasing, running back and forth, negativism) as a way of terminating aversive behaviors that have been issued from a parent (e.g., scolding, issuing negative commands). The result is that the parent eventually withdraws his/her demands in order to terminate the child’s aversive behavior. For the child, her or his aversive behavior has terminated the original aversive parental behavior (e.g., scolding). For the parent, her or his acquiescence has terminated the child’s aversive behavior (e.g., whining). In this manner, the parent’s attempts to discipline the child often have the effect of reinforcing the child’s coercive behaviors and subsequent aggression (Patterson 1982, Patterson et al. 1991).

The coercive behaviors on the part of the child may escalate as this family interactional pattern continues, from minor coercive behaviors (e.g., whining) to more intense (if less frequent) coercive behaviors (e.g., hitting, temper tantrums, stealing). Indeed, coercive exchanges can be thought of as a series of “rounds” that escalate in severity and increase the probability that one or more family members (the child or the parent) will react aggressively (Robinson and Jacobson 1987).

Studies of parent–child interactions during early childhood suggest that punitive parenting and a tendency to emotional reactivity in the child may be mutually reinforced, leading to greater parent–child conflict and poor emotion regulation over time (Scaramella and Leve 2004). A number of studies provide validation for the association between highly coercive family relationships and antisocial/aggressive behavior (Burgess and Conger 1978, Lobitz and Johnson 1975, Patterson 1976, 1980, 1982, Patterson and Cobb 1971, Patterson et al. 1991, Robinson and Jacobson 1987, Snyder 1977, Wahler and Dumas 1987) and substance abuse (Hops et al. 2000) in offspring. For example, members of families containing children who are socially aggressive or who steal engage in higher rates of aversive behavior than do members of families containing normal children (Patterson 1982, Patterson et al. 1991). Mothers of children with conduct problems have been found to be more likely to initiate and continue unpleasant, aversive interchanges with the index child than mothers of normal children (Lobitz and Johnson 1975, Patterson 1982, Patterson and Cobb 1971). In addition, children with behavior problems are more likely to continue coercive interchanges with their mothers than are control children (Patterson 1982). Perhaps as a consequence, coercive relationships are frequently associated with depression in one or more family
members (Patterson 1980). It is not clear, however, whether coercive processes simply reflect the parents’ response to the child’s aggressive behavior or whether these processes play a direct role in causing aggression in the child.

**Communication Deviance**

Wynne and Singer (1963a, b) observed that the transactional processes of families of concurrently hospitalized patients with schizophrenia were often unclear, amorphous, fragmented, or unintelligible. In their research, these high levels of CD discriminated parents of children with schizophrenia from parents of children with borderline personality, neurotic, antisocial, or autistic disorders and of normal children (Singer and Wynne 1963, 1965a, b). The authors believed that CD was present before, and was etiologically associated with, the appearance of schizophrenia in genetically prone offspring. Direct evidence for this view derives from one high-risk study demonstrating that high levels of CD among parents of disturbed but nonpsychotic adolescents predicted the onset of disorders within the schizophrenia spectrum (i.e., schizophrenic or schizotypal, schizoid, paranoid, or borderline personality disorders) among these adolescents who had follow-up into adulthood (Goldstein 1987). However, CD may covary with the severity of the offspring’s diagnosis rather than the presence of a specific diagnosis. Indeed, high CD is characteristic of the parents of bipolar, as well as schizophrenic, offspring (Miklowitz et al. 1991) and may increase with severity of offspring psychopathology (i.e., from normal to neurotic to borderline to psychotic) (Wynne et al. 1977).

Although CD appears to be correlated with a diagnosis of schizophrenia, a number of mechanisms may explain this association (Miklowitz and Tompson 2003). Two in particular have garnered empirical support. First, CD in parents may be internalized by the child and lead to the development of difficulties in processing information and perceiving reality; thus, CD contributes to the development of vulnerability to schizophrenia. This view receives modest support from the diagnostic discrimination studies and high-risk study cited above. More recently, Wahlberg et al. (1997) demonstrated that individuals with high genetic risk (having a schizophrenic biological parent) who were exposed to high CD adoptive parents were at particularly high risk for developing thought disorder. Second, CD may reflect an indirect expression of the genetic vulnerability to schizophrenia in parents of affected offspring. One study suggested that parents of schizophrenic patients who show high levels of the perceptual-cognitive forms of CD also show dysfunction on information-processing tasks (Wagner et al. 1986). Two other studies demonstrated cross-generational correlations between CD in parents and degree of attentional and information-processing dysfunction in their diagnosed schizophrenic offspring (Nuechterlein et al. 1989, Asarnow et al. 1988). However, levels of CD are not correlated with the presence or absence of DSM-III-R (APA 1987) diagnoses in parents (current or past) (Goldstein et al. 1990).

In summary, studies of CD suggest that high levels of CD correlate with severe psychiatric conditions and may influence the development, and possibly the course, of these conditions. It is premature to refer to CD as an etiological agent in schizophrenia or other disorders.

**Expression of Affect**

All messages have cognitive and emotional content and overtones, but it is conceivable that family units could be relatively proficient in one area while deficient and disturbed in the other. Negatively toned communication can consist of intensely personal, “character-assassinating” remarks (e.g., “You are an incompetent person”) or, alternatively, an excessive number of specifically delineated criticisms of a person’s behavior (e.g., “You never try hard in school”). It is also common to observe “negatively escalating cycles,” which become increasingly pejorative and personal as they continue. Often, these cycles are accompanied by negative, defensive, nonverbal behavior that also escalates (Hahlweg et al. 1989, Simomeau et al. 1998).

**Couples**

When spousal communication is extremely negative or pejorative, the marriage is likely to be at high risk and symptoms may develop in one or both mates. Because the direct and indirect expressions of affects such as anger, hostility, and resentment seem central to both poor problem-solving behavior and low marital satisfaction, we isolate affect from cognition for conceptual clarity and emphasis. Depressed and distressed spouses are more likely to express dysphoric affect than are nondepressed and nondistressed spouses (Hautzinger et al. 1982, Kowalkik and Gotlib 1987). In addition, distressed spouses exchange more negative affect than do nondistressed spouses (Schaap 1984, Coyne et al. 2002). As the EE literature indicates, a subgroup of spouses of depressed patients demonstrate critical remarks and nonacceptance of the mate, which are associated with poor prognosis for the depressed partner (Hooley et al. 1986).

Distressed couples, compared with nondistressed couples, are more affectively reactive to ongoing negative and positive stimuli (Jacobson et al. 1980, 1982). There is a greater likelihood that distressed spouses, compared with nondistressed spouses, will react negatively to displeasing behavior by the other spouse (Jacobson et al. 1980). This type of behavior predicted marital dissatisfaction in at least one longitudinal study (Markman 1981). The interactions of spouses headed for divorce are frequently characterized by pervasive negativity, including global criticism, expressions of contempt and defensiveness, and eventual refusal to interact (Driver et al. 2003).

A circular interactional pattern has been described in the literature on depression and marriage. This pattern resembles the coercive processes of families of aggressive children described above. In this marital pattern, negative communication and a lack of positive support and responsiveness on the depressed spouse’s part elicit hostility and withdrawal from the nondepressed partner, which in turn elicits more depression and more calls for reassurance by the depressed individual (Baucom and Epstein 1990, Birchler et al. 1975, Hinchcliff et al. 1978, Klerman et al. 1984). Spouses of a depressed mate rated as high in EE showed interactions characterized by negative and critical remarks, frequent disagreement with the depressed spouse, and nonacceptance of what the mate has said to them. In turn, depressed mates showed low frequencies of self-disclosure and high levels of neutral nonverbal behavior (Hooley 1986).

Depressed couples, compared with control subjects, are characterized by negative affect after interactions and
negative appraisals of the other spouse’s behavior (Gotlib and Whitaker 1989). Couples with a depressed partner exhibit negative and asymmetrical communication, with frequent expression of dysphoric and uncomfortable feelings (Hautzinger et al. 1982). In general, depressed couples tend to be characterized by negative affect (Kowalik and Gotlib 1987).

Families
As in couples, families may be able to communicate clearly but may deliver messages that are highly critical, pejorative, hostile, or villifying. Although some degree of this type of communication is to be expected in every family, an excessive number or duration of negatively toned interactions may become associated with disturbance in one or more family members. Although it is not unusual for one family member to be the primary source of hostile emotional communication and another the primary target, it is also common for other family members to “aid and abet” these types of interchanges.

Throughout childhood the emotional quality of parent-child interaction impacts development and adjustment. Negatively toned parental feedback may lead to the internalization of a more negative self-concept and set the stage for future difficulties (Harter 1999), and exposure to intense and on-going parental conflict may lead to the development of poor emotion regulation and increased risk of psychological symptoms (Cummings and Keller 2006). In addition, parental expression of affect in parent-child interactions may be strongly linked to children’s social development and acceptance by peers over time (Isley 1996, Parke et al. 2006). Expressions of positive affect among mothers predict greater acceptance by the child’s peers, whereas expressions of negative affect among fathers predict poorer acceptance by peers (Isley 1996).

There is now evidence from more than 35 studies to suggest that excessive criticism, hostility, or emotional over-involvement (high EE), or a combination of these, from parents, as measured by the individually administered Camberrwell Family Interview (Vaughn and Leff 1976b), are prospectively associated with the course of numerous psychiatric problems, as rated by observational coding systems (Birchler and Hooley 1998), including schizophrenia (Miklowitz and Tompson 2003, Kavanagh 1992, Parker and Hadzi-Pavlovic 1990), bipolar affective disorder (Miklowitz et al. 1988), nonpsychotic depression (Hooley et al. 1986, Vaughn and Leff 1976a), alcoholism (Fichter et al. 1997, O’Farrell et al. 1998) and obesity (Fischmann-Havstad and Marston 1984). High family EE is also predictive of poorer outcome among individuals undergoing behavioral treatments for obsessive-compulsive disorders, agoraphobia (Chambless and Steketee 1999) and posttraumatic stress disorder (Tarrier et al. 1999).

A separate, but related, domain of inquiry has concerned negatively toned family interactions. In a 15-year prospective study of nonpsychotic, disturbed adolescents (Goldstein 1987), affective negativity in parent to adolescent interactions (i.e., criticism, guilt induction, intrusiveness) was independently predictive (along with the family’s level of CD) of the severity of outcomes observed in these adolescents at 15-year follow-up. Two other studies (Doane et al. 1985, Miklowitz et al. 1988) using similar procedures and construct definitions, found that the level of affective negativity during interactions between parents and their schizophrenic or bipolar offspring, measured after the patient’s hospital discharge, was associated with the risk of the patient’s relapse at a 9-month follow-up. Studies are mixed about whether the success of family interventions is mediated by the reduction of negative family attitudes and interactions. In one study, Doane et al. (1986), in a controlled family treatment study, found that family treatment was effective in delaying new episodes of schizophrenia if it was successful in reducing the number of critical comments and intrusive, “mind-reading” statements observed among parents during pretreatment family interaction assessments. However, Leff et al. (2003) found that whereas reducing family EE or reducing patient contact with high EE relatives mediated the efficacy of family treatment for schizophrenia, this was not the case for couples treatment for depression. In sum, there is strong evidence for the prognostic validity of negative affective communication or attitudes within families containing a patient with a severe psychiatric illness, but the mechanisms of action of family based interventions vary with the nature of the condition.

Problem Solving
Problem solving is a general construct relating to the manner in which two or more people define conflict issues, consider alternative lines of action, and proceed to the most optimal action as demanded by a problem situation (Falloon et al. 1984). The impact of negative life events within a relational unit may be impacted by the strategies they use for approaching and solving problems (Cohan and Bradbury 1997). It is common for families seeking treatment to be unable to solve major family problems—this is often the very reason that they seek treatment. However, when families do not have the skills for solving problems in general, such as the ability to define a problem or generate possible solutions, they may become “stuck” in ways that prevent the growth or individuation of one or more members.

Couples
Distressed couples manifest more negative communication and fewer positive communication behaviors when solving problems, as rated by observational coding systems (Birchler et al. 1975, Gottman 1979, Gottman et al. 1977, Revenstorf et al. 1984, Schaap 1984). Problem-solving behavior is less frequent (Biglan et al. 1985), more negative (Vincent et al. 1975), and often results in ineffective solutions in distressed couples (Winemiller and Mitchell 1994). Problem escalation (i.e., problem solving by spouse 1, followed by negativity by spouse 2, followed by negativity by spouse 1) is also more characteristic of distressed couples (Revenstorf et al. 1984). Furthermore, negative reciprocity, involving mutual fault finding, cross-complaining (Gottman 1994), and the communication of global and negative attributions, is also greater among distressed than nondistressed couples (Billings 1979, Gottman et al. 1976, Margolin and Wampold 1981, Rausch et al. 1974, Revenstorf et al. 1984). Positive reciprocity is more characteristic of nondistressed couples (Revenstorf et al. 1984), but not in all samples (Margolin and Wampold 1981). Poor problem-solving skills in interactions, combined with lower levels of positive affect, strongly predicts deterioration in marital satisfaction among newlywed couples over time (Johnson et al. 2005). In addition, poor problem-solving ability has been associated with depression among spouses (Basco et al. 1992).
Conflict resolution is a specific subset of problem-solving behaviors (i.e., resolving differences of opinion between two or more people). Whereas all couples display conflict, it is especially common among couples (Gottman et al., 1977, Margolin and Wampold, 1981, Hahlweg et al., 1984a, 1984b). The reciprocity of negative rather than positive behavior distinguishes distressed couples from nondistressed couples (Revenstorf et al., 1984, Schaap 1984, Driver et al., 2006).

From a longitudinal perspective, predictors of short-term and long-term marital satisfaction appear to be different (Gottman and Kroff, 1989, Driver et al., 2006). Although disagreement and angry exchanges relate to dissatisfaction in the short run, they may not be harmful across time. In contrast, longitudinal marital deterioration is best predicted by defensiveness, whining, stubbornness, and withdrawal from interaction. Stonewalling, in which one partner adamantly refuses to discuss a problem, is particularly associated with divorce (Gottman, 1994). Interestingly, in a large longitudinal study of marriage and economic stress, Conger et al. (1999) found that effective problem solving among couples reduced the impact of marital conflict on perceived marital satisfaction. Thus, when couples are able to generate and implement effective problem solutions, disagreement may not lead to unhappiness with the relationship.

Families
When a family is deficient in solving problems, the tension level in the household is likely to increase and conflict between members tends to escalate. In such a family climate, children do not learn to recognize the steps necessary to solve interpersonal problems and may develop psychiatric or their social or academic competence may suffer (Blechman, 1990).

In general, a strong relation has been found in the literature between the way parents solve socialization problems of their children and the cognitive abilities of these children (Baumrind, 1975, Bee et al., 1982, Bradley and Campbell, 1980, Gottfried and Gottfried, 1983, Hess and Shipman, 1965). For example, in a study of school-age children, Blechman and McEnroe (1985) found that those families that built the tallest towers in a cooperative task were those with the most academically and socially competent children.

Compared to nonclinic families, families seeking help at a mental health clinic demonstrated less problem solving (Krisley and Bry, 1991) and more disagreement (Whittaker and Bry, 1991) in the problem-solving discussions. Poor family problem solving has been noted in the families of youth with attention deficit hyperactivity disorder and oppositional defiant disorder. Both treatments used behavioral techniques to enhance problem-management skills. While the two treatments did not differ in outcomes, they both produced positive change in observed and self-reported measures of youth conflict. Thus, teaching problem-solving skills to parents and adolescents may address family conflicts associated with disruptive behavior disorders.

Diagnosis of Relational Disorders
Although research on structure, expression of affect, communication, and problem solving in couples and families has led to a greater understanding of the difficulties that can afflink these relational units, specific relational problems have only been recently included as a diagnostic entity in the DSM (see DSM-IIIR, DSM-IV-TR) and clear diagnostic criteria have yet to be developed. Current textual descriptions of these conditions refer to impairment in the “pattern of interaction” in these relational units (DSM-IV-TR, p. 736), reflecting the broad range of specific difficulties subsumed under this diagnostic entities.

Phenomenology
Five specific relational disorders are noted in DSM-IV-TR (see the definition section earlier in the chapter). Family relational problems and partner relational problems are delineated below. These difficulties may also afflink relational units in the presence of a mental disorder or medical condition. The phenomenology of sibling relational problems and relational problems with other individuals has not been well explored.

Partner Relational Problems
Clinical experience and the research descriptions suggest that marital (and couples) relational problems manifest in the following ways:
1. Couple does not clarify mutual requests, provide information, or accurately describe problems.
2. Spouse or spouses verbalize underlying attributions, assumptions, and expectations that are negative (e.g., spouse is globally negatively intentioned) or exaggerated (e.g., spouses should never fight).
3. Affective communication is characterized by negative affect (e.g., anger, hostility, jealousy), critical remarks, disagreement with spouse, and nonacceptance of what the mate has communicated.
4. There is a low frequency of self-disclosure of thoughts, feelings, and wishes.
5. Couple demonstrates inadequate problem solving characterized by poor problem focus, mutual criticism and complaint, and negative escalation.
6. Couple displays sequences of negative communication characterized by criticism, disagreement, negative listening, and refusal to agree.
7. Couple avoids conflict by withdrawal, lack of discussion, and subsequent nonresolution.

Associated Features
Associated features of marital communication difficulties or disorders include poor marital satisfaction, psychiatric disorder in one or both spouses, threatened and contemplated separation and divorce, or concentration and job performance difficulties.

Family Relational Problems
Family relational problems manifest as the following:

1. Family is unable to communicate clearly, cannot communicate closure, or cannot share a focus of attention (CD).
2. Family communication is characterized by unidirectional hostility or frequent criticism or by bidirectional, negatively escalating cycles of pejorative or critical comments.
3. Parent–offspring relationships are characterized by overprotectiveness, overconcern, unnecessarily self-sacrificing behaviors, intrusiveness, or overdependence (emotional overinvolvement).
4. Parent–offspring interchanges are marked by negatively reinforcing coercive cycles that tend to perpetuate antisocial or aggressive behavior in one or more family members.
5. A broad array of family problems cannot be solved because of the family’s inability to agree to try to solve, define, generate, or evaluate solutions to, or implement solutions to, existing problems.

Associated Features
The associated features of parent–child communication difficulties or disorders include adolescent acting out and disruptive behavior, major psychiatric disorders in one or more family members (i.e., schizophrenia, affective disorder), poor parental morale, and parenting dissatisfaction.

Assessment of Relational Disorders

Overall Relationship Functioning
The Global Assessment of Relational Functioning Scale (GARF; Group for Advancement of Psychiatry 1996) included in DSM-IV-TR is a 1–100 scale of overall relationship functioning, akin to the Global Assessment Scale for individuals. Recent studies have indicated that the GARF is reliable in clinical settings (Dausch Miklowitz, and Richards 1996, Rosen et al. 1997, Hilsenroth et al. 2000, Mottarella et al. 2001), and that GARF ratings are correlated with self-report measures of relationship functioning (Wilkins and White 2001), and that changes in GARF scores are positively associated with both client and therapist-reported change in treatment and with treatment satisfaction (Ross and Doherty 2001).

Structure
Family structure can be measured with self-report instruments as a control subscales on both the Family Assessment Measure (Skinner et al. 1983) and the Family Environment Scale (Moos and Moos 1981) and as an organizational subscale on the latter. In interaction research, it has been recommended (Markman and Notarius 1987) that dominance be measured in terms of procedures that assess the consequences of behavior (e.g., influence of dominant one on decisions) rather than on who speaks first and/or for the greatest proportion of the time.

Parental overinvolvement has been defined in various ways in the psychiatric literature (Parker 1982), but the criteria used within the EE coding system (Leff and Vaughn 1985) are the best operationalized: a tendency to be overprotective of, overly concerned about, overly controlling of, or domineering toward an offspring; to engage in numerous self-sacrificing behaviors in the name of good parenting (e.g., the parent denies himself or herself social relationships to satisfy the needs of the offspring); to engage in intrusive, boundary-crossing, or mind-reading interactions with the offspring; and to react to minor events affecting the offspring with exaggerated emotional responses and to over dramatize these incidents. In return, the offspring may react with overt struggles for independence or autonomy or, in contrast, passivity, withdrawal, and overdependence. Parker and coworkers’ (Parker et al. 1979) well-validated Parental Bonding Instrument provides a working definition of over-protection: parental overcontrol, intrusion, and excessive contact, and preventing the child from acting independently (Parker 1983).

Communication
Communication is measured in family and marital questionnaires—for example, with a communication subscale of the Family Assessment Measure (FAM-III; Skinner et al. 1983); the Dyadic Adjustment Scale (Spanier 1976) with a dyadic cohesion subscale; and the Primary Communication Inventory (Navran 1967) with its verbal communication subscale.

Ratings of interpersonal behavior involving self-disclosure, positive solution, negative solution, justification, direct expression, criticism, critique, positive communication, and negative communication can be seen as relating to the general category of communication skills (Markman and Notarius 1987). Numerous coding systems have been devised to examine particular communication processes within families (Kerig and Lindahl 2001). As an example, Kategoriensystem für Partnerschaftliche Interaktion (KPI; Hahlweg et al. 1984a) codes, such as self-disclosure (“I’m too angry to listen to...”)
to you at the moment”), positive solutions (“I’ll sweep the floor if you play with the kids”), problem description (“We’ve got a problem with the kids”), and disagreement (“That’s not true”), provide evidence of communication skills. The brief Communication Patterns Questionnaire (Heavey et al. 1996) has shown strong associations with both marital satisfaction and the constructiveness of spousal behavior during videotaped problem-solving discussions.

Recently, measures have been developed to evaluate partner’s cognitions that have been associated with communication difficulties. The Relationship Attribution Measure (Fincham and Bradbury 1992) assesses the manner in which partners assign responsibility for their spouse’s behavior. The Marital Attitudes Survey (Pretzer et al. 1991) assesses spouses’ attributions regarding their partners attitudes and behaviors in the relationship and expectancies about the possibility of relationship change.

Communication deviance consists of two primary components: disorders of linguistic-verbal reasoning (i.e., unfinished phrases, unintelligibility, odd word usage) and perceptual-cognitive disturbances (i.e., inability to integrate multiple pieces of information into a coherent message; inability to perceive and describe an object or concept accurately). The majority of studies of CD have relied on transcripts of projective test (i.e., the Rorschach Inkblot Test or Thematic Apperception Test) responses from parents as the primary data source for coding CD. One study (Velligan et al. 1990) found a correspondence between levels of parental CD as measured in a projective and an interactional context, although not all forms of CD were measurable in both contexts.

Measurement of coercive processes usually requires that the observer watch the family interact directly, because these processes often occur on a behavior-exchange rather than a verbal-exchange level. In this way, coercive processes are to be distinguished from affectively negative verbal exchanges.

Perhaps the best-known system for coding coercive processes is the Family Interaction Coding System (Patterson 1982, Patterson et al. 1969). It is a home observation system in which positive, neutral, and negative behaviors on the part of all family members are coded sequentially by live observers, in contiguous 6-second time blocks. Interrater reliabilities for the system have been consistently high across studies (Robinson and Jacobson 1987).

Expression of Affect

Family and marital questionnaires address affect in terms of expressiveness, a subscale of the Family Environment Scale (Moos and Moos 1981); affective communication, a subscale of the Marital Satisfaction Inventory (Snyder 1979, 1981); affectional expression, a subscale of the Dyadic Adjustment Scale (Spanier 1976); and the affective expression and affectional expression, a subscale of the Dyadic Adjustment Scale (Spanier 1976). Studies using self-report instruments have also yielded interesting results (Hooley and Teasdale 1989, Kreisman et al. 1979, Haas et al. 1988).

For interaction research, it has been recommended that affect be coded by observing the affective content of both verbalizations and nonverbal behavior (Markman and Notarius 1987). Negatively toned family communication has been measured primarily via structured interviews of individual family members (i.e., the Camberwell Family Interview for rating EE) or observation and coding of family interactions (e.g., the affective style coding system or the KPI).

Problem Solving

On self-report instruments, the Marital Satisfaction Inventory (Snyder 1979) has a problem-solving communication subscale. In addition, problem-solving behavior is often sampled directly, both as it spontaneously occurs in free-flowing discussion and in the context of solving assigned tasks such as card sorting (Olveri and Reiss 1981) or the revealed differences technique (Strodbeck 1951) and its modifications (Ferreira 1963).

Conflict is measured on the dyadic consensus subscale of the Dyadic Adjustment Scale (Spanier 1976) and on the conflict subscale of the Family Environment Scale (Moos and Moos 1981). It is measured in terms of disagreement about finances, sexual dissatisfaction, and conflict over child-rearing on the Marital Satisfaction Inventory (Snyder 1979), the Conflict Tactics Scales (Straus 1979) obtain self-report on strategies used to resolve conflicts in families, including reasoning, verbal aggression, and violence.

Interactional ratings of conflict are similar in content. Interactional ratings of agreement, disagreement, sequences of positive and negative communication, such as on the KPI, are all under the umbrella of conflict. Conflict has also been operationalized in interactional speech samples as speech interruptions, simultaneous speech, agreement/disagreement ratios (Jacob 1975, Riskin and Faunce 1970) and failure to reach agreement (Farina 1960).

In the family literature, measurement of problem-solving skills has typically involved an unstructured or semi-structured task such as a family problem-solving discussion (Strodbeck 1954) or a tower-building game (Goldberg and Maccoby 1965). Criterion variables generated by these tasks have included tabulations of problem-solving enhancement statements during interaction (Doane et al. 1986), the number of tower blocks the family puts together (Blechman and McEnroe 1985), or the family’s self-rated satisfaction with the problem-solving task (Blechman and McEnroe 1985). In other studies (Reiss et al. 1986), problem solving may be measured by such attributes as the level of coordination shown by family members in solving a given problem (e.g., recognizing patterns in an array of symbols) or the family’s openness to new information from each other or its ability to change solutions to accommodate new data (“delayed closure”).

Epidemiology of Relational Disorders

The raw frequency of relational disorders (broadly defined) in the general population is unknown. No epidemiological studies have been done, in part because of the absence of accepted diagnostic criteria for these disorders. There are rather vague “proxies” of relational disorders that are useful in making estimations of their prevalence, such as the approximate frequencies of divorce in the general populous (40–50% of all couples; Kreider and Simmons), of marital violence (12–33% of couples; Sagrestano et al. 1999), or of child abuse and neglect (an estimated 3.6 million cases investigated by CPS agencies during 2005). Factors such as divorce or violence, however, are best thought of as relational events rather than relational disorders. A single incident of
marital violence does not necessarily signal the presence of a family relational disorder (in the absence of confirmatory information), nor is a diagnosable relational disorder in a spousal couple necessarily associated with divorce. Thus, the prevalence of specific types of relational disorders, as described in this chapter, is difficult to estimate.

A further difficulty in making these estimations in the normal population is that certain of the constructs conveyed, such as expressed emotion (EE) as based on the Camberwell Family Interview (Vaughn and Leff 1976a, 1976b), assume the presence of a psychiatric disorder in an index family member. Also, the goal of EE and other family psychopathological studies has been to examine family attribute–outcome relationships on a within-group basis in psychiatric disorders rather than to making comparisons between families of psychiatric patients and nonpsychiatric control subjects. Thus, data are lacking on the frequencies of high-EE attitudes or other family attributes in normal control groups.

Estimating the normal prevalence of EE is aided by the availability of the Five-Minute Speech Sample EE coding system (Magana et al. 1986), which simply requires that the parent talk for 5 minutes, uninterrupted, about the relationship with an index offspring (ill or well). This coding system yields an EE rating that has a close but not perfect correspondence (72–89.7%; Magana et al. 1986; Moore and Kuipers 1999) with EE ratings based on the Camberwell Family Interview, the traditional measure of EE (Vaughn and Leff 1976b). Stuebe et al. (1993), in a population-based study of inner-city preadolescents, found that 22% of parents of children with no psychiatric disorders met the Five-Minute Speech Sample coding criteria for high EE, in contrast with 40% of parents of children having one or more psychiatric disorders.

A number of studies of CD have examined rates of speech deviance in the normal population, but most have selected normal comparison groups to match with samples of patients with schizophrenia and, thus, do not reflect a random cross section of the population. Given this limitation, high levels of CD (defined in various ways) appear to occur in about 16% (range 0–39%) of the parents of normal persons, compared with about 63% (range 19–76%) of the parents of patients with schizophrenia (Miklowitz and Tompson 2003, Miklowitz and Stackman 1992). The significant variability in rates across samples probably reflects differences in methods of assessing CD as well as sampling variabilities.

The paucity of studies on the frequency of family relational disorders points to the need to develop strict operational criteria for these disorders and to conduct epidemiological studies using random sampling techniques, much as is done for individual disorders. The availability of epidemiological data would allow us to determine not only the need for treatment of specific relational disorders but also their comorbidity with individual or other relational disorders, their associated features, and the social conditions under which they are most likely to arise.

Specific Axis I and II disorders may have a strong impact on and be strongly impacted by relational problems. For example, much has been written on the association between depression and interpersonal problems (Joiner and Coyne 1999) and between parental depression and youth psychopathology (Goodman and Gotlib 2002). Clinicians should be alert to the probable comorbidity between relational disorders and mood, Axis II, disruptive behavior, and substance use disorders.

**Treatment**

**Specific Goals of Treatment**

The primary goal of treatment is to bring the relational unit to a more satisfying, organized, and less conflictual level of functioning. The mediating goals of treatment are focused on improvement in the specific areas of functioning of the relational unit (i.e., structure, communication, affect expression, problem solving). In relational units where one member is suffering from a mental disorder or medical condition (e.g., schizophrenia, depression, childhood disruptive behavior disorder), additional goals include the reduction of individual symptoms and improvements in psychosocial functioning.

**Treatment Format**

Relational problems are best observed and treated directly in a family format in which the conflicted family members are present with the therapist. However, there may be certain situations in which relational problems are more conducive to change within an individual treatment format. For example, relational problems related to an individual with a mental disorder (e.g., a 25-year-old son with schizophrenia, in conflict with his mother and father) may in some cases be approached by individual sessions with the affected person. Further, when one adult in a family unit is depressed, individual interpersonal or cognitive psychotherapies may be used and focused on conflict resolution. Parent training is often conducted with parents alone, and skills are then implemented with youth at home.

**Treatment Strategies and Techniques**

The specific techniques available to family therapists can be divided into five categories: psychoeducational, cognitive-behavioral, structural, strategic-systemic, and insight-oriented. Psychoeducational approaches are most helpful when there is a family member with a specific medical or psychiatric disorder, and the family can utilize information on how to manage the disorder with the least tension and stress on the patient (Clarkin 1989). Cognitive-behavioral techniques are useful in improving communication and problem-solving skills and the positive interactive behaviors in marital-family units. Structural and strategic-systemic approaches are most useful in rearranging the repetitive interactions in a family that constitute the boundaries and alliances in the social system.

In practice, there are many common elements and much eclectic usage of strategies and techniques across the various schools of family intervention. Family therapy shares many of the common treatment elements with other forms of psychotherapy. All psychosocial treatments require the development and maintenance of a good patient–therapist relationship, or therapeutic alliance. There is an assumption that most patients experience some degree of corrective emotional experience, or reliving of significant life experiences in the presence of an empathic therapist who demonstrates new ways of relating. In this context, the patient (or patients) is able to identify with the therapist and utilize the behaviors
discussed and modeled. In all forms of psychotherapy, there is a certain degree of transmission of new information. The learning can be about methods of behavior, ways of thinking, or increased awareness of complex emotions. Most therapies involve some shaping of people's behavior through implicit and explicit rewards for behavior considered appropriate, and discouragement of behaviors considered harmful. This shaping can occur through advice, suggestion, persuasion, role playing, and practice.

**Standard Approach to Treatment**

There is increasing evidence for the efficacy of family and marital interventions in the treatment of a broad range of relational problems and psychopathology, and extensive reviews of this literature can be found elsewhere (Pinsof and Wynne 1995, Glick 1999, Sholevar and Schwoeri 2003). However, several specific questions about treatment efficacy can be asked here in reference to the previous review of relational difficulties:

1. Do the specific relational difficulties (i.e., structure, communication, affect, and problem solving) respond to intervention?
2. Do the individual disorders associated with relational problems (e.g., schizophrenia, affective disorders, adolescent delinquent behavior) show improvements in illness course when the relational problems are at least part of the focus of intervention?

**Empirical Investigations of the Efficacy of Family or Marital Treatment**

**Partner Relational Difficulties**

Difficulties between romantic partners, including marital distress and relationship conflict, are most often addressed using couples-based interventions. A number of treatment models have been articulated and investigated, including “emotionally focused marital therapy” (Johnson 1999), “insight-oriented marital therapy” (Snyder and Wills 1989) and “integrative behavioral couples therapy” (Christensen et al. 2006). Recent meta-analysis examining findings from 15 couples intervention studies found that, when compared to no treatment, couples therapy resulted in significant positive changes in partners’ behavior and evaluations of the relationship (Dunn and Schwebel 1995).

The most well-researched therapy is behavioral marital therapy (BMT; Alexander et al. 1994, Christensen et al. 1995), in which partners are coached on methods for increasing positive interactions and decreasing aversive ones, improving communication and enhancing problem solving. BMT has received extensive empirical support and testing, and recent meta-analytic data suggest only moderate effect sizes (Shadish and Baldwin 2005). However, longitudinal follow-up studies conducted by Jacobson et al. (1984, 1987) indicate that almost half of the couples engaged in these interventions fail to make clinically meaningful improvement and many fail to maintain gains achieved within these interventions.

Modifications of the BMT approach have included a greater emphasis on facilitating “acceptance” of one’s partner (Lawrence et al. 1999) and increasing motivation for change (Cordova 2004). This revised model, called the integrated behavioral couple therapy, had a comparable overall outcome to traditional behavioral couple therapy over 2 years. However, couples gained in satisfaction sooner in integrated behavioral couple therapy than couples in traditional behavioral couple therapy, and generally remained more stable over 2 years (Christensen et al. 2006).

Few studies have compared these models directly and thus it is not possible to match them to specific couples. One study found that emotionally focused marital therapy was superior to behavioral marital therapy for the treatment of moderate marital distress (Wood et al. 2005).

**Parent–Child Difficulties**

Difficulties between parents and their children or adolescents can take the form of child and adolescent behavioral problems; child abuse and neglect; and difficulties, deficits, or excesses in parenting. Parent Training approaches have been developed to address both the treatment and prevention of parent–child difficulties. Videotaped modeling interventions, such as those developed by Webster-Stratton (2003) provide cost-effective and efficacious methods for training parents in setting limits, using effective discipline, problem solving, and promoting interpersonal and academic skill development. These modeling approaches include specific interventions for early childhood (ages 2–7 years) and school-aged youth (ages 5–12 years) and target parents, teachers, and children for training. Kazdin et al. (1992) have also developed and tested manualized problem-solving skills training and parent management training interventions for youth ages 7–13 years with conduct problems. The problem-solving skills training uses cognitive-behavioral strategies to assist the child in negotiating interpersonal situations. Parents were included in sessions to assist the therapist and to foster problem-solving steps in the home. In parent management training, the parent was seen individually to improve child-rearing practices and to use contingencies to support prosocial behavior by the child. Although in a clinical trial both treatments demonstrated improved child functioning and increased social competence, a combination of the two treatments resulted in more marked changes in child and parent functioning and placed a larger proportion of children within the range of nonclinical levels of functioning. Parent Training has shown moderate effects for the treatment of child abuse, but efficacy is improved by including home visits, training in the home, and individual as well as group sessions (Lundahl, Nimer, and Parsons 2006). Individual sessions may be particularly important when treating economically disadvantaged families (Lundahl, Risser, and Lovejoy 2006). This and other studies (Sayger et al. 1988, Singer et al. 1989) suggest that family therapy has promise in reducing specific problematic child behaviors with behavioral techniques and that the parents have a better personal adjustment after learning parenting skills.

Parent–child interaction therapy (PCIT; Querido and Eyberg 2005) was developed for children ages 2–7 with disruptive behavior problems. Using both didactics and coaching sessions, the therapist helps parents enhance both the parent–child relationship and the implementation of behavior management strategies. During coaching sessions, the therapist provides feedback and direction from behind a one-way mirror directly to the parent (using an “ear bug”).
as he/she interacts with the child. PCIT is associated with significant improvements in children’s behavior, decreases in parental distress, and increased positive expression in parent-child interactions.

Nonspecific Parent–Adolescent Conflicts and Adolescent Behavioral Problems and Delinquency
Numerous studies have been completed in this area. The most well-researched intervention for serious behavior problems in youth is the aforementioned parent-management training. This intervention has shown efficacy in the treatment of a wide range of serious behavior problems in youth, including conduct problems and delinquency, oppositionality, and aggressive behavior (Kazdin 1997, Mabe et al. 2001). Henggeler et al. (1992) developed multisystemic therapy and applied it to the treatment of juvenile offenders with records of serious crime. Multisystemic therapy had a duration of 3 months and employed intervention strategies similar to those in family and behavioral therapy (i.e., individualized treatment plans sometimes involving home visits in addition to therapy meetings). Compared with “treatment as usual” (incarceration or probation), multisystemic therapy led to greater reductions in both incarceration and criminal behavior for boys in the treatment condition. Long-term follow-up studies suggest sustained effects of multisystemic therapy (Schaeffer and Borduin 2005).

Substance Abuse
More research is needed with patients and families suffering from alcohol and substance abuse, a major problem area in our society. The existing family studies show some promise for the use of family therapy (Friedman 1989, Liddle 1999, Stanton and Todd 1979, 1982) but it may be most effective with specific subgroups, possibly with younger abusers still at home and where family assets are substantial. Substance abuse is often comorbid with conduct problems in youth, and the few available studies suggest that both individual cognitive therapy and behaviorally oriented family therapy may be associated with significant improvements for youth with comorbid conduct and substance use problems (Azrin et al. 2001).

Eating Disorders
The early theoretical and clinical work of Salvador Minuchin, one of the leaders of the family movement, focused on eating disorders. Recent research lends increasing empirical support to the role of family-based treatments in a comprehensive strategy for addressing eating disorders. Russell et al. (1987) randomly assigned patients (57 with anorexia nervosa and 23 with bulimia nervosa) to either family therapy or individual supportive treatment after an inpatient treatment intended to bring the patient to normal weight. The goal of treatment was to help the family support the patient’s recovery from eating disorder. After 1 year of treatment, the patients were reassessed for body weight and menstrual functioning. Treatment effects were still apparent at a 5-year follow-up (Eisler et al. 1997). The results are relevant to differential treatment planning, as those patients whose eating disorder was not chronic and had begun before the age of 19 years were more effectively treated with family therapy.

Comparing conjoint family therapy to a separated family therapy (in which parents and the adolescents were seen in separate sessions), Eisler et al. (2000) found separated family treatment to be associated with significant reductions in parental EE and greater symptoms improvements. Robin et al. (1999) compared Behavior Family Systemic Treatment to individual treatment for anorexia nervosa. While improvements were apparent in both treatments, symptom improvement was greater in the family intervention. Group family treatments have also been shown to facilitate recovery from anorexia nervosa (Geist et al. 2000).

Schizophrenia
Family treatments for patients with schizophrenia and their families have been found to have strong beneficial effects. There are at least eight studies of family interventions of longer term (i.e., 9 months or more) duration (Barrowclough and Tarrier 1990, Falloon et al. 1985, 1987; Falloon and Pederson 1985, Hogarty et al. 1986, 1991, Leff et al. 1982, 1985, 1989, Randolph et al. 1994, Tarrier et al. 1988, 1989, 1994, Xiong et al. 1994). The majority of these treatments focus on providing psychoeducation and enhancing communication problem-solving skills in a family context. Although these multifaceted interventions show strong effects on patient outcomes, more limited provision of psychoeducation to families does not appear to impact patient outcomes (Lam 1991, Pitschel-Walz et al. 2001). Enhancement of coping skills within the family appears to be a necessary component of these interventions.

Illustrative is the treatment approach articulated by Anderson et al. (1986; Hogarty et al. 1986), which is broad based and extensive, including survival skills workshops for the families, reentry of the patient into the family, enhancing work and social adjustment of the patient, problem solving, and maintenance of therapeutic gains. Results of randomized studies (Hogarty et al. 1986, 1991) show the superiority (in terms of relapse rates and social adjustment of patients) of family therapy to individual social skills training or a no-therapy, medication-only control group during a 2-year follow-up.

Both the number and the quality of family therapy studies are impressive. The family treatments have been manualized, and the existing outcome literature suggests that family therapy is a useful and effective part of the overall treatment of these seriously disturbed individuals (Bellack and Mueser 1993, Goldstein and Miklowitz 1995, Penn and Mueser 1996). Recent studies suggest that multiple family group interventions may be more cost-effective than those focused on individual family units (McFarlane 1995). Focus on the individual family units may be appropriate early in the course of illness, whereas later on, a multiple family group format may be optimal (Tompson et al. 1996).

Questions remain as to the most important focus of family intervention (e.g. lowering EE versus increasing family coping) and at what point in the illness of the patient are families most likely to respond positively to family intervention.

Mood Disorders
Most of the studies of family intervention in families where one member is suffering from a mood disorder have been done in the marital treatment format, reflecting the age
at onset of affective disorders (Beach and O'Leary 1992, Jacobson et al. 1991). There are a few studies involving families. Data from the Cornell Medical Center study of inpatient family intervention with patients with bipolar or major depressive disorders (Clarkin et al. 1990) suggest that inpatient family intervention may be fruitful for some subgroups. These patients and their families were randomly assigned to psychoeducational inpatient treatment with or without family intervention. At both 6- and 18-month follow-up times, patients who received family intervention showed better outcome than those without it. These treatment effects were limited, however, to the female bipolar patients. In contrast, those patients with unipolar depression did better without family intervention. Studies with outpatient samples suggest that, when depression is accompanied by marital distress, couples-based treatments may be superior to cognitive behavioral treatments (Beach and O'Leary 1992). The few studies of family treatment with depressed adolescents suggest that cognitive behavioral interventions may be superior to family-based interventions during this developmental stage (Brent et al. 1997). However, family-based interventions may be optimal for preadolescents (Asarnow et al. 2005).

Clarkin et al. (1998) randomly assigned 33 married bipolar I patients to a psychoeducational marital therapy with medication or to a standard medication treatment. Although the marital treatment did not have differential effects on relapse rates, it was associated with gradually improving Global Assessment Scale scores over 11 months of treatment. Patients in marital treatment also were more consistent with their use of medication than those in standard medical treatment.

Two clinical trials examined a family-focused treatment for adult bipolar I patients (Miklowitz and Goldstein 1997) following hospitalization for mania or depression. Family-focused treatment, delivered along with mood stabilizing medication and consisting of education, communication skills training, and problem-solving skills training, was found to reduce risk of both relapse and hospitalization when compared to treatments consisting of crisis intervention and medication (Miklowitz et al. 2003) or individual therapy and medication (Rea et al. 2003). FFT was also superior to brief psychoeducation in hastening time to recovery among bipolar, depressed patients in the Systematic Treatment Enhancement Program for Bipolar Disorder (Miklowitz et al., in press). More recently, this work has been extended to adolescents with bipolar disorder (Miklowitz et al. 2004, Miklowitz et al. 2006).

Summary
The research suggests that family treatment is effective with schizophrenia, affective disorders, adolescent and child acting-out difficulties, and eating disorders (Pinsof and Wynne 1995). In terms of strategies and techniques used in the family and marital treatment formats, there is substantial evidence for the effectiveness of cognitive-behavioral and psychoeducational techniques, with few data on the other approaches. Future studies should compare the efficacy of (and estimate the relative treatment effect sizes attributable to) family therapy versus competing therapies (i.e., individual or group therapies). Future research should also determine the optimal format in which to administer family treatment (i.e., home-based versus clinic-based; individual families versus multifamily educational groups).

Medical Comorbidity
Relational problems can co-occur with virtually any general medical condition. In most cases, it can be convincingly argued that a medical condition in one member (e.g., cancer) can promulgate relational problems between this member and other members or between two other members of the family (e.g., a husband and wife who develop marital problems stemming from disagreements as to how to treat their daughter's juvenile-onset diabetes). In some cases, the relational problems may have prognostic value for the course of the medical condition and thus may become a focus of ancillary treatment.

Numerous attempts have been made to link the family constructs listed earlier (i.e., structure, communication, expression of affect, and problem solving) to the concurrent severity or future outcome of various medical conditions. For example, Koenigsberg et al. (1993) examined levels of spousal EE in relation to glucose control in diabetic patients. The number of critical comments made by the spouse during a modified Camberwell Family Interview significantly predicted glycosylated hemoglobin levels (a measure of glucose control) in the patient, the latter having been measured for the 2- to 3-month period before the interview. Levels of emotional overinvolvement among spouses were not predictive. Among youth with cystic fibrosis, family relationship quality during a family intervention task was positively associated with adherence to medical treatments. However, the problem solving did not add to the prediction of adherence above relationship quality (DeLambo et al. 2004).

Vitaliano et al. (1989) reported that spouses of Alzheimer's disease patients (with early- to middle-stage dementia) infrequently (22%) exhibited high-EE attitudes on the Five-Minute Speech Sample (a measure that may underestimate the prevalence of high-EE attitudes relative to the Camberwell Family Interview). When spouses had high EE, they reported more depression, feelings of being burdened, anger turned inward, and problems in anger control than those who had low EE. However, it was also the case that patients paired with high-EE spouses were rated by interviewers as having higher levels of functional impairment than those paired with low-EE spouses. During a prospective follow-up, the Alzheimer's disease patients with high-EE spouses showed more externalizing behavioral problems (i.e., paranoia, violence, and wandering) than those with low-EE spouses, despite the absence of differences over the follow-up in levels of cognitive decline (Vitaliano et al. 1993).

There is evidence that medical conditions often covary with communication disturbances in marital couples. For example, Hudgens (1979) found that 18 of 24 couples in which one member had chronic pain had communication disturbances. However, extensive communication between spouses where one has chronic pain also carries certain disadvantages. For example, in one study, higher levels of agreement between pain patients and their spouses in their evaluations of the severity and impact of the pain problem predicted poorer outcome for the pain disorder (Swanson and Murata 1980; Roy 1988). Chronic pain in one family member requires changes in the structure or hierarchical organization of the family, such that the well spouse must
become the primary wage earner or take over a considerable proportion of the family’s decision-making (Rowat and Knafl 1985). Perhaps in couples where spouses strongly agreed they had made an accommodation to the chronic pain and therefore had reduced motivation to address this condition.

There is evidence that enhanced family problem solving may be a protective factor in the course of certain medical conditions. Using a pattern-recognition procedure, Reiss et al. (1986) examined the problem-solving interactions of families in which one member had end-stage renal disease requiring long-term hemodialysis. The authors found that high family scores on “delayed closure” during the problem-solving task—indicating that the family was “environmentally sensitive,” open to new information in choosing solutions, and willing to introduce new solutions when new information was available—predicted fewer medical complications in the affected family member during a 9-month follow-up period.

While family-based interventions for medical conditions have not been sufficiently investigated, there is some evidence of their utility, particularly for the treatment of chronic childhood diseases (Campbell and Patterson 1995) where families are faced with numerous challenges in promoting health and adjusting to often complex medical regimens. Family-based psychoeducational interventions in the treatment of sickle cell disease (Kaslow et al. 2000) have resulted in greater disease knowledge among participating families when compared to treatment as usual. In a clinical trial, behavior family systems therapy with adolescents with insulin-dependent diabetes mellitus resulted in lower diabetes-specific family conflict and improvements in the parent–child relationship when compared to treatment as usual and to an educational support group (Wysocki et al. 2000).

It is clear that chronic and progressive medical illness co-occurs with a host of relational difficulties that may in some cases bode poorly for the outcome of the medical condition. In most instances, these relational disturbances seem to arise in reaction to the medical condition and are not apparently causally related to the disorder itself. Familial or marital intervention in medical conditions may, however, reduce the tension in the household and the level of burden and psychosocial stress experienced by the caretaking family member(s), which could in turn provide a more protective environment for the ill family member.

Case Example
The following case description illustrates one manifestation of relational problem. The case is conceptualized with regard to the relational constructs reviewed above, including structure, communication, expression of affect, and problem solving. A typical treatment strategy is then briefly presented.

Clinical Vignette
Mr. A, a 26-year-old man employed as an air conditioning mechanic, was referred by a local marital therapist with the recommendation of individual therapy for anxiety and adjustment disorder. He arrived 10 minutes early for his session and entered the therapist’s office with an air of anxiety and deference to the therapist’s authority. He immediately leaped into his personal story, almost before the therapist could sit down. He and his wife of some 15 months had just had their first child, a son, born 3 weeks ago. In addition, the couple had moved to the suburban area only 6 months ago, and the move had taken them from a city apartment near the wife’s parents to a suburban single-family house located near his parents. The problem, according to Mr. A, was his wife’s overattachment to her parents and her related dislike of his parents, which spilled over into resentment toward him. This disturbance had led Mr. A to be distracted and less efficient at work. His boss, who had paternal concern toward him, noticed his upset and suggested that he seek counseling. Mr. A had gone to a marital therapist, who told him he could do nothing because the wife refused to attend marital sessions. Mr. A indicated that his wife would not see the present therapist either. The therapist asked Mr. A to talk to his wife about the current therapy and ask her if the therapist, in the effort to help Mr. A, could telephone her. The wife agreed to telephone and, subsequent to the call, was willing to come to the therapist’s office for an individual session.

She arrived for her appointment, accompanied by Mr. A, who was holding their 4-week-old son, who appeared well-clothed and content. The wife’s story was consistent with that of her husband’s but quite different in emphasis and focus. She indicated that her husband’s loyalty and involvement with his parents, especially his mother, had come to a head with the birth of their son. The mother-in-law had “invaded” her hospital room the day after the son’s birth and insisted that Ms. A come directly from the hospital after discharge to her house with the newborn child and stay with her. Although Ms. A had difficulty opposing her mother-in-law, she stated that she was going to their own home and that her own mother would be with them for a couple of days. After receiving that message, the mother-in-law instantly became quiet and abrupt. Indeed, Ms. A felt that from that time on, Mr. A, influenced by the mother, had also become aloof and abrupt with her.

Diagnostic Evaluation
Currently, Mr. A exhibits the following diagnoses using the multiaxial system:

- **Axis I**: 309.24 Adjustment Disorder with Anxiety
- **Axis II**: 799.90 Diagnosis Deferred
- **Axis III**: None
- **Axis IV**: Recent move to new neighborhood; birth of child
- **Axis V**: GAF = 60

Mr. A’s symptoms of anxiety and agitation in the last few months were clearly related temporally to the difficulties with his wife and their families of origin and possibly exacerbated by the birth of his son. Currently the patterns of interaction within the relationship are impaired and the relational unit has become increasingly distressed and dysfunctional. In addition to Mr. A’s distress, Ms. A has been isolated and experienced depressed mood after the birth of her child. Thus, the most efficient approach to the individual difficulties lies in an evaluation of the family situation.

Mr. A clearly has a partner relational problem. In terms of the family relational constructs enunciated in this chapter, the situation can be described as follows. In terms of family structure, there are diffuse and nonfunctional boundaries between the young couple and the families of origin. Mr. A and Ms. A are both heavily involved with...
their families of origin, possibly to the neglect of their marital relationship. In particular, Mr. A’s pattern of communication with his mother and related lack of intimacy with his wife is quite disturbing to Ms. A. In terms of communication, interactions between husband and wife are characterized by periods of silence and then bursts of verbal exchange characterized by suspicion and accusation, especially about their families of origin. Both parties feel aggrieved and each feels victimized by the other’s parents.

In terms of expression of affect, the interactions between the two are characterized by negative emotions of anger, sadness, and mutual withdrawal. Very little positive affect is expressed. In terms of problem solving, few attempts are made to resolve the difficulties, and daily issues become not occasions for normal problem resolution but rather, opportunities for mutual recrimination. For example, Mr. A recently decided that he did not have the time to drop off their annual tax return to the accountant, so he took the returns in an unsealed envelope to his mother to deliver. The wife was enraged at this manner of delivering their private financial accounts and once again accused him of being too close to his parents. This “lack” of problem-solving ability is “situation specific,” however, as both husband and wife can effectively solve problem in other settings (e.g., work).

**Treatment**

Treatment began with further individual meetings with both spouses. These meetings focused on understanding the history of the relationship, the nature of interactions and expectations within each of their families of origin, and exploration of their individual goals. Conjoint sessions with husband and wife then focused on their relationship. The tasks of therapy can be understood in terms of the previously discussed constructs. First, in terms of structure, the partners needed to develop clearer boundaries within and around the relationship. The therapist repeatedly pointed out how both partners had brought with them, from their families of origin, certain expectations for family relationships. As these expectations became clearer to both partners, the therapy shifted to helping the partners examine their relationship and develop clearer boundaries between the husband/wife subsystem and their respective parents. Second, in terms of communication, listening skills were practiced by each, as the other partner explained his/her expectations and hopes in the relationship. The partners were taught specific communication skills, including giving and receiving positive and negative feedback and making requests for behavior change. Homework assignments between sessions were used to practice and generalize these skills.

In terms of affect expression, improvements in communicating led to decreases in negative exchanges. In addition, partners were encouraged to review the positive aspects in each which had initially brought them into the relationship and, through homework, to practice noticing and commenting on positive aspects of each other’s behavior. Finally, problem-solving skills were taught and practiced in and out of sessions. As the couple tried to establish clearer boundaries within and around the relationship, numerous opportunities arose to practice solving problems related to their families of origin.

Organization and Economics of Mental Health Treatment

Section VII

Section VIII
Introduction
Psychiatrists and other mental health professionals require an understanding of the organization and financing of care. The structure and funding of mental health care continues to change sometimes predictably but many times unexpectedly. For instance, at the same time that federal, state, and local budgets are strained by health care costs the largest expansion in nearly four decades in the federally funded Medicare program, the MMA (Part D) was approved by Congress in December 2003 (Huskamp 2005). Experiments with expansion of benefits such as the Federal Employees Health Benefit Program’s implementation of parity for mental health and substance abuse treatment (Azrin et al. 2007, Goldman et al. 2006) as well as continued attempts at cost containment, and care management through managed care entities in both the public and private sector continue to shape psychiatric care.

New techniques for reforming and improving the care of people with psychiatric disorders require knowledge and skills well beyond basic clinical training. At the same time, as the rate of treatment of mental disorders appears to be increasing from 20.3% between 1990 and 1992 to 32.9% between 2001 and 2003 (Kessler et al. 2005) concerns about access and appropriateness of treatment remain (New Freedom Commission on Mental Health 2003). Psychosocial interventions which provide some of the greatest hope for recovery for people with the most disabling disorders are often the most difficult to access, deliver, and fund within the present structure of the mental health care system.

Astrachan (1980) commented on this issue more than two decades ago, noting that “the future of health care organizations lies primarily in their members’ clinical competency and commitment to excellence in practice, but is also dependent on their knowledge of such administrative tasks as planning and budgeting, and their management of the physical plant and its employees.” Yet the developments in recent years have made these issues even more pivotal than Astrachan anticipated. Economic trends have led to a more significant “corporate presence” in health care, and psychiatry is no exception. Judgments about care of patients and treatment options must consider the cost and efficacy of care, both in the short term and in the course of illness.

The dominant approach to financing health care in the US is private insurance. This is a recent development compared with the long history of mental health care. Since its origins in a single plan at Baylor Hospital in 1929, developed to serve teachers at the University of Texas, private insurance coverage has grown dramatically to become the major financing approach for health care in the US. Fee-for-service reimbursement for physicians and hospitals has been the prevalent payment approach. As this chapter will indicate, these strategies are changing rapidly. Regulation of insurance coverage has increased and will continue to evolve as health care is reformed. Providers are joining together or being organized in groups to compete for contracts based on specialty expertise, price, and efficiency. Hospitals and indeed other services are increasingly owned and influenced by investors. The advent of third-party reviewers and “gatekeepers” of care further complicates the organization and financing of care. Finally, payers and patients search for arrangements to increase quality and decrease costs, leading to continual competition among purchasers and providers. In this environment, the psychiatrist must be aware of financing, payment, and organizational issues to survive and to provide quality care. Current trends also imply that psychiatrists will function less as solo practitioners but more as diagnosticians and care coordinators as well as caregivers.

Historical and political factors have also shaped the evolution of the modern mental health system. To appreciate...
the impact and effect of these factors, some historical review is essential. An understanding of the dynamics and tensions that continue to shape how care is provided is an important complement to clinical skills and an appreciation of organizational and financing factors.

Historical Trends and Forces in Mental Health

Although theories and practices in mental health care can be traced back to thousands of years, historical trends with clear relevance for today can be found starting in the 18th and 19th centuries. As with many other aspects of culture, European influences are generally thought to have had the most impact on the US practices and have certainly been documented best.

Important European Influences

Most descriptions of European mental health practices that influenced care in Colonial America focus on the philosophy of moral treatment articulated by Philippe Pinel in France and Samuel Tuke in England. Moral treatment rested on a belief that mental illness resulted in large measure from environmental influences and that it was curable through humane care in an orderly, calm, and supportive milieu. One of the most powerful images of mental health reform is of Pinel removing the chains from the insane in 17th century France. Tuke was a founder of the York Retreat in York, England, and wrote of this experience in his 1813 work, Description of the Retreat. The York Retreat, a Quaker charitable institution, was established in the moral treatment philosophy as a facility where the mentally ill could be removed from the stresses and strains that were thought to cause mental illness and receive support and instruction in a complete milieu of supportive treatment.

It is clear that Pinel’s treatment philosophy and the concept of the retreat or asylum had a significant effect in America. Such facilities as the Pennsylvania Hospital (1751), McLean Hospital in Boston (1818), and the Hartford Retreat (1844) were established in this tradition. In fact, the American Psychiatric Association had its roots in this tradition, being formed in 1844 as the Association of Medical Superintendents of American Institutions for the Insane.

These highlights of professional leadership in mental health care must be viewed in the context of the political and social influences on mental health care. How did the cruel custodial facilities develop that required the heroic reform of Pinel, and what patterns of community neglect required the creation of asylums? How did these trends influence the course of the US mental health care well into the 20th century? Foucault (1965) has chronicled these developments and shown that the treatment of the mentally ill in Europe was dominated by social trends and public opinion. For example, as leprosy virtually disappeared in Europe the well endowed charitable institutions found themselves without a population to serve. Many leprosariums, with their tradition of serving a feared and alienated population turned to providing asylum for the mentally ill. Thus, at their inception many facilities for people with mental illness were already associated with negative attributions of contagion and the need to isolate the mentally ill from the rest of society not only for the person’s benefit but to protect others.

Other less positive European traditions from this era foreshadow troubling current US concerns and problems as well. Another pattern of “care” in Europe was a form of banishment—the ship of fools. Captains of these vessels would accept deranged persons for a fee and ferry them about the waterways of Europe, sometimes to be discharged in an isolated city, sometimes consigned to permanent life on the ship, and usually to be the object of amusement and ridicule when such a ship with its strange cargo came to port. These traditions helped form the fear and misunderstanding about mental illness and its care that still persist as a stigma that may keep sufferers from seeking help.

An important English tradition also formed a foundation element for the US patterns of care. This was the evolution of the “Poor Laws,” the common law guarantee of relief for the unfortunate. The notion of relief or general welfare payments, although clearly humanitarian, would come to have several other effects. For one, just as in the unfortunate US experience with deinstitutionalization hundreds of years later, this form of “outside relief” would make other forms of care somewhat less necessary, because after all “the mentally ill were getting some form of help.” The concept of relief, when framed as “welfare” in the US political context, would create further image barriers for the mentally ill. From the “fear image” derived from care in the leprosariums to the “fool image” of the ship of fools to the “incompetence image” of welfare, the mentally ill were acquiring a heavy burden that would still have an impact in 21st century America.

This background also puts the work of reformers in perspective. Pinel and Tuke—and later reformers in America—were on the one hand heroic. The conditions they sought to change, whether inside confinement or outside abandonment, were rooted deep in political and social tradition. Making change in mental health programs was then, as now, a difficult proposition. The work of Pinel and Tuke was also the product of new political values being formed in the era of the American and French revolutions. The values of moral treatment were closely linked to, and indeed drew from, the deeper values that led to these broad cultural changes. This is a final lesson in reform from the European tradition—that clinical reform efforts are linked to contemporary social and political reforms. Patterns of care do not exist in isolation. Understanding these linkages, particularly as they have evolved in the US, is essential to understanding how patterns of care have developed and continue to evolve. These influences on mental health care are summarized in Table 86–1.

Early Developments in Mental Health in the US

The trends and themes of mental health care in the US developed from these European roots. Before the moral treatment
era, there was little organized care. Mentally ill individuals were the responsibility of their family or village. Before the industrial revolution, in a time when manual labor was the order of the day, many individuals survived without any care other than the therapy of hard work. The predominant early “mental health service” that developed in the early 1800s was the almshouse, a kind of reform designed to provide some care, albeit undifferentiated care. As might be expected, the mentally ill did not fare well in such settings, although they constituted a large proportion of those placed in such settings.

The moral treatment era brought the first in a series of largely unsuccessful reform efforts that would characterize the US mental health policy. The early asylums, such as those at Philadelphia, Boston, and Hartford, were philanthropic institutions. During the mid-1800s, the impulse was to establish asylums as a governmental responsibility. Grob (1966) has chronicled this history in depth, focusing on the history of the Worcester (Massachusetts) State Hospital, established in 1830, as the first public asylum in that state. The founding of the hospital was clearly associated with the kind of charitable and humane impulses that derived from the leadership of Tuke and Pinel and recognized the failure of both outside relief and the almshouses to meet the specialized needs of mentally ill individuals. The founding concept was clearly that a kind of social and rehabilitative acute care, in a serene setting, would help people recover. The early records suggest that the hospital was in fact successful. Many patients were discharged, and few in the earliest days stayed for purely custodial care.

The Growth of Asylums
The early successes of asylums like Worcester, coupled with growing public awareness of the conditions in the almshouses and the social reform impulses of the Jacksonian era, led to a boom in the construction of state hospitals. The catalyst was an extraordinary advocate named Dorothea Dix, a retired Boston schoolteacher who made improving the lot of the mentally ill her second career. During this period, she visited every state legislature east of the Rocky Mountains and succeeded in convincing most to construct a state hospital. Buoyed by this success, she lobbied Congress to enact land grant legislation that would allow the federal government to grant land to each state; the land was to be sold and the proceeds used to establish hospitals. In almost all the early public asylums, the construction was financed as a fundamental state responsibility. In Ohio, for example, the operation of asylums was mentioned in the state constitution as a fundamental state responsibility.

The Erosion of Community Responsibility
This problem was exacerbated by another “reform” effort. In almost all the early public asylums, the construction was underwritten by the state legislature, which also provided a small appropriation for operations—a kind of “seed money.” These funds were not intended to be adequate for the full operation of the hospitals; because mental health problems occurred in most communities and the almshouses had been a local responsibility, communities were to be billed for the costs of caring for their indigent citizens. At one level, this represented the type of intergovernmental tension that has seemed to plague mental health care ever since. Yet it was a productive tension, because it created a disincentive for the long-term institutionalization of disabled persons; but the arrangement was a problem for the hospitals. Collecting funds from all the towns was inconvenient, and the rates tended to lag behind costs, especially during a period of rapid inflation.

These problems led to the well-meaning State Care Acts, enacted in many states in the second half of the 19th century to solve this problem. Because the institutions were competently run and were essentially a state responsibility, and because the local fees were inconvenient, having the state simply assume financial responsibility was an obvious solution. In Ohio, for example, the operation of asylums is mentioned in the state constitution as a fundamental state responsibility.
This wave of legislation created an obvious problem. Addressing the inconvenience of local responsibility by virtually wiping it out, the State Care Acts eliminated any incentive for local care and created a particular pressure for the institutionalization of long-term disabled individuals. The short-term orientation of the hospitals was subtly erased, and the ability of disabled persons to persist by doing manual labor in an agrarian society was also permanently altered by the onset of the industrial revolution. As a consequence, the history of mental health care in the US in the latter part of the 19th century was disastrous.

This era involved a confluence of negative forces that eroded the moral treatment reforms. The perverse financial incentives created by the State Care Acts led to increased rates of institutionalization. These pressures, combined with the “silting in” effects of disabled patients who could not be discharged, sent the levels of hospitalization soaring. Grob (1966) analyzed the forces that contributed to the decline of moral treatment, using Worcester State Hospital as a case study. Additionally, he noted that the increasing size of the institution created a self-reinforcing dynamic of regimentation and efficiency, which reduced quality of care and increased the custodial nature of the hospital. Grob also found that an evolution in the professional role of psychiatry also contributed to the decline of the hospital. In a perverse way, the profession’s focus on psychiatry as a “scientific discipline” estranged the leadership of the hospital from the civic and volunteer leaders who had contributed to its early development. In addition, an emphasis on somatic treatments produced empty results, because they had little to offer at the time and tended to undermine the optimism and egalitarian values that moral treatment had contributed to hospitals.

Cultural and class factors also contributed to a changed and problem role for state hospitals during this period. Not only did the industrial revolution put a premium on skilled labor and begin to hasten the decline of communal, agrarian lifestyles (which were much more suited to sustaining the mentally ill), but the demands of the industrial workplace and the ability of disabled persons to persist by doing manual labor in an agrarian society was also permanently altered by the onset of the industrial revolution. As a consequence, the history of mental health care in the US in the latter part of the 19th century was disastrous.

The Mental Hygiene Movement
Fortunately, as Morrissey and Goldman (1984) pointed out, the emerging pattern of the US mental health policy shows that cycles of neglect do lead to cycles of reform. Although the professional leadership of the time was crucial in the next wave of reform, especially in the “mental hygiene” approach of Adolph Meyer, it was once again a partnership between citizens and professionals that stimulated change. In this case, the citizen leader was Clifford Beers (1908) whose book *A Mind That Found Itself* focused national attention on the deterioration of the hospitals but also showed the possibilities of recovery. Beers had been hospitalized at both the Hartford Retreat and the Connecticut Asylum for a period of several years and described graphically the degradation and horrors of this experience. He also detailed his positive experiences with recovery, speaking perhaps to the American fascination with the “self-made man” but connecting powerfully to the enthusiasm and new theories of mental hygiene.

As Morrissey and Goldman (1984) noted, this cycle of reform was linked to both a new model or theory and a preference for particular facilities—the psychopathic hospital and the child guidance clinic. Like the moral treatment approach, both facilities and indeed the mental hygiene movement were eventually founded on the same rocks of the intractability of long-term mental illness. The mental hygiene approach—like moral treatment—emphasized brief special treatment with an emphasis on returning to normal functioning. No concept of long-term care had yet developed. The approach was also linked to the dominant cultural values of the time, emphasizing science, order, and classification. Thus, the psychopathic hospital was affiliated with academia and focused on applying diagnostic and treatment expertise to mental illness.

The first prominent facilities included Pavilion F, opened in Albany in 1902, and the Boston Psychopathic Hospital, opened in 1912. The child guidance clinic emphasized similar themes but clearly also stressed the value of early, clinically based intervention as a preventive strategy. Child guidance clinics were developed in a number of cities during the same period. The movement also led to an emphasis on professionalism that extended beyond psychiatry, with the founding of the first school for psychiatric social work at Smith College in 1928.

Like the moral treatment era, the mental hygiene reforms drew on emerging cultural and political developments, included a core treatment philosophy, and emphasized new types of treatment facilities. However, this cycle of reform also emphasized acute care and therefore failed to meet the challenge of the long-term major mental illnesses. In fact, by this emphasis, the approach did not have much impact on the state hospitals, which had essentially become long-term care facilities. Mental hygiene, therefore, did not succeed as comprehensive reform.

The World Wars and Psychiatry
Mental health issues emerging from both World War I and especially World War II had a dramatic effect on policy. Working with traumatized soldiers in World War I, Thomas Salmon described the “shell shock” syndrome. Drawing from the mental hygiene theory of early intervention, brief treatment that focused largely on separating the soldier from stress—although not removing him too far from the front lines and maintaining high expectations of early recovery and return to battle—proved successful. Thus, crisis intervention methods were literally developed in the heat of battle.

These same methods were used and further refined during World War II. In addition, however, events in World War II thrust mental health issues into a more prominent national light. A high proportion of those men found unfit to serve in the military were screened out because of mental illness—almost two million individuals. Later, questions were raised about the accuracy and adequacy of screening (Deutsch 1949), but the number of individuals rejected for service was large. In addition, about 40% of the military personnel dismissed from active duty as unfit to serve were
discharged because of mental illness. These extraordinary rates of illness came to public and policymakers’ attention at precisely the time when the federal government was poised to affect mental health policy and as the country was poised to enter a period of prosperity and of a relative focus on domestic affairs. As a result, Congress passed the Mental Health Act in 1946, creating the National Institute of Mental Health (NIMH) as a focal point for research, professional training, and policy development.

**Mental Health Policy in Postwar America**

The pace and complexity of change in health and mental health care since World War II have been dizzying. Because we are closer to this period, it may be more difficult to see it clearly. Certainly, opinions still vary on the dynamics and nature of many developments, starting with deinstitutionalization (viewed by some as necessary social progress and by others as abandonment). It is wise to recall some of the persistent trends in the US mental health policy that have their roots in European and Colonial traditions, for these trends are still shaping policy and patterns of care in ways that are not immediately evident to the casual observer.

One fundamental and recurring tension is between mental illness and “madness” or between clinical and sociological understandings. Viewed from a clinical perspective, the creation of asylums in the European reformation or in 19th century America was simply the development of an improved treatment system. Yet, as Foucault (1965) and Grob (1966) have shown, these institutions served other purposes. The early asylums filled the niche that had been vacated by leprosy, with certain consequences in terms of stigmatizing the mentally ill. America’s asylums were not able to hold their desired quality and acute care orientation for more than a decade or two and quickly became places where the wayward and others unable to play a productive role in the industrial revolution were “stored.” Indeed, this trend was accelerated, as (Grob 1983) shown, by the unintended actions of the medical superintendents and their loss of contact with citizen leaders. Thus, an awareness of the balance between clinical requirements and initiatives and their social context and meaning is essential in viewing modern developments.

A second problem trend has been to base reform on an incomplete or unrealistic view of mental illness and therefore its treatment requirements. This is a central point made by Morrissey and Goldman. They emphasized that the first two “cycles of reform” in America (the asylum and the mental hygiene movement) inaccurately conceived of most serious mental illness as acute or temporary, leading to treatment strategies that were ultimately doomed to failure. This limited view would vex another reform era yet to come—the community mental health movement of the 1960s and 1970s.

Finally, the role of the public sector in the US mental health care has been significant; the tensions between states and the federal government, and increasingly between the public and the private sectors, has never been good for patients. This pattern was established with Pierce’s veto of the land grant hospital construction legislation in 1854, ceding responsibility to the states, and with the State Care Acts that weakened local responsibility for the mentally ill. Whereas these actions clearly set in place a dynamic of primary state responsibility, the weakened local role encouraged the creation of custodial institutions as a mode of service and did not resolve the federal–state tensions that are so much a part of the US political life. With the establishment of the NIMH in 1946, the federal government reasserted its interests. The Great Society programs that were to follow, in an era of federal activism, would muddy this picture even more.

**The 1950s: New Treatment Technology, Federal Activism, and the Civil Rights Movement**

The decade of the 1950s served as an incubator for major changes. The impact of these changes was later felt in a more substantial fashion. Three such developments listed in Table 86–3, were most significant: the introduction of psychoactive medications, an emerging activism on the part of the new federal mental health bureaucracy, and the growth of the civil rights movement and its use of the federal courts.

**Chlorpromazine and the State Hospitals**

Chlorpromazine was first used in the state hospitals in the early 1950s, with several significant effects. The first effect was an immediate clinical impact. The census of the state hospitals peaked at a significant 550,000 individuals in 1954 and has declined every year since then. This decline in the 1950s was clearly related to the impact of chlorpromazine, which provided enough relief to enable the discharge of many patients. The second impact of this new technology was a renewed optimism about mental health treatment—the same sort of optimism that had characterized the moral treatment and mental hygiene eras.

**Civil Rights: Social Change and the Role of the Courts**

The emergence of the civil rights movement was marked by the Brown v. Board of Education lawsuit filed in Topeka, Kansas, in 1954. Several features of this movement affected mental health reforms in a substantial way. First, the values of human rights served as a foundation for reformers who saw a better life for institutionalized mentally ill individuals. Yet again, emerging community values affected developments in mental health. The second feature of the civil rights movement related to mental health was just as critical—the use of the federal courts to solve a problem that legislatures and the general public were not yet ready to address. Although federal court litigation in mental health did not begin in earnest for another two decades, the seeds of change had been planted.

**An Activist Federal Government**

After the veto of Dorothea Dix’s legislation by President Pierce a century earlier, the federal government had retreated
from any substantial role in mental health for decades, but the national experience during the two world wars and the establishment of the NIMH marked a change in this pattern. Although the leadership role in service provision clearly rested with the states, there was a mood for change marked by the trends of the 1950s. The passage of the Mental Health Study Act in 1955 marked this new activism. The legislation charged the Joint Commission on Mental Illness and Mental Health with a national study to develop and recommend policy.

**The 1960s: Transformational Change and Unintended Consequences**

The National Commission issued its ambitious report, *Action for Mental Health*, in 1961. Formed in the new environment of federal activism and optimism about mental health treatment, the report proposed a broad approach to change. Its recommendations included dramatic increases in funding for mental health care, aggressive approaches to recruitment and training, an increased emphasis on acute and community care, and movement away from the custodial state hospitals. A mental health clinic to serve each population base of 50,000 persons across the country was proposed, as were expanded programs for persons with long-term mental illness.

These recommendations fell on the ears of a receptive president and Congress. President Kennedy was clearly interested in mental retardation and mental health, and these recommendations were less controversial than the changes in other areas of domestic policy that the country confronted. Optimism about treatment and community care, the need to reform the state hospitals, and the ability of the federal government to change things formed the context for reform. The result was the 1963 Community Mental Health Centers Act, with its focus on developing locally managed, and broadly focused mental health centers across the country. The legislation represented the federal government’s most ambitious effort in mental health care but was seriously flawed from the outset. In a sense, the most notable success of the legislation was simply its passage, marking public support and recognition of mental health treatment. The legislation eventually led to the establishment of more than 700 centers (although about 2,600 would have been needed to cover the country) and also stimulated passage of parallel legislation and initiatives at the state level.

There were several design flaws in the community mental health center (CMHC) legislation as well. There was a “disconnect” between the growing antipathy for state hospitals and the desire for community care. The centers were to provide a wide variety of community services, but the emphasis was on acute treatment, not the kind of rehabilitation, support, and care needed by the long-term patients in hospitals. Two other aspects of the legislation heightened the separation between the poor, disabled patients of the hospitals and the new centers. First, the federal chauvinism of the time had resulted in the establishment of the CMHC program (like the antipoverty programs of the time) as a federal–local partnership, with the states only tangentially involved. As a result, the state mental health agencies (SMHAs), which ran the hospitals, were cut out of the picture with respect to the CMHC priorities and oversight. Second, the funding mechanism for the CMHC establishment was limited to construction grants and time-limited (7 years) start-up funding.

As during the moral hygiene era, a substantial federal role in funding mental health care was not politically acceptable. (Perhaps it would be more accurate to say that an explicit role in funding mental health was not acceptable, because the soon established Medicaid program eventually became the nation’s single largest mental health funder.) As a result of the limited federal financing and the resulting pressure on CMHCs to establish “financial viability,” the centers needed to find paying customers. This tension, coupled with the orientation toward broad mental health concerns rather than the care of the seriously mentally ill, led most centers to limit their role as providers for formerly hospitalized patients, focusing instead on other paying customers and efforts. Although probably almost all the centers cared for some formerly hospitalized patients, it was not their central concern. Coupled with the limited population coverage of the new centers, this meant that the program was in no way adequate to support the downsizing of the state hospitals that had probably been intended—and was certainly about to happen.

**Medicaid, Transinstitutionalization, and Privatization**

Although the passage of the CMHC legislation is generally viewed as the major federal mental health initiative of the 1960s, it is likely that the enactment of Medicare and Medicaid was more influential, at least in terms of the numbers of patients and practitioners who were affected. Medicare (Title Eighteen of the Social Security Act) was enacted in 1966 to provide insurance to persons older than 65 years eligible for Social Security. It was amended in 1972 to provide for all those older than 65 years, with a premium mechanism to cover costs. At the same time, eligibility was extended to disabled workers and their beneficiaries as well as to patients with chronic renal disease. Medicare rapidly became the dominant insurance mechanism and therefore a major force in health financing policy.

However, Medicaid (Title Nineteen of the Social Security Act), also enacted in 1966, had a dramatic effect on seriously mentally ill individuals almost immediately. Medicaid was designed as a health insurance program for the poor and disabled, primarily covering acute care. However, Medicaid also provided financing for long-term care by coverage of nursing homes. (Both Medicare and Medicaid were thus focused in large measure on the elderly and, together with other measures, had a substantial positive effect on older Americans—a major success of the War on Poverty and Great Society programs, whereas most came to be regarded as failures.)

For the reason that its eligibility included seriously mentally ill individuals, almost all of the patients who were made destitute by their illness, Medicaid was a viable financing vehicle. Since it was largely a federally financed program (the federal share ranged from a minimum of 50% for wealthy states up to 75% for poor states), it was attractive to states. Also, because it covered nursing homes, which substituted for state hospitals for the care of many disabled patients, Medicaid set up an enormous transfer of care. The
Medicaid also had a dramatic effect at the “front door” of the state hospitals by financing hospital care for psychiatric patients in general hospitals, both in “scatter beds” (medical–surgical beds occupied by patients with psychiatric diagnoses) and in distinct psychiatric units. The availability of Medicaid reimbursement aided a dramatic expansion of general hospitals as a primary locus of acute psychiatric care. Between 1965 and 1980, the volume of psychiatric admissions to these units increased from about 700,000 annually to approximately 1700,000 annually (Kiesler and Sibulkin 1987). Through the 1980s and 1990s the Medicaid reimbursement, available to general hospitals but not to IMDS, continued to fuel expansion of psychiatric care in general hospitals with discharges from these units growing from 1.4 million in 1988 to 1.9 million in 1994 (Mechanic 1989). Conversely, the Medicaid “IMD exclusion” helped further diminish the role of state hospitals in acute care. State hospitals provided 63% of 24-hour hospital and residential treatment episodes in 1955 but only 10% by 1998 (Manderscheid et al. 2000). A recent study shows this trend has continued through 2002 (Watanabe-Galloway and Zhang 2007). From 1995–2002, in the US, the discharge rates from general hospitals for people with severe mental illness increased by 34% from 29.1 discharges per 10,000 adult population in 1995 to 39.2 discharges per 10,000 adults in 2002. Rates increased mainly for blacks, young males, and for the northeast and south regions. Rate increases were also highest for individuals covered by private insurance and in proprietary hospitals. Government payers while still representing the largest funder at 60.6% in 2002 had fallen from 70.3% in 1995.

The Erosion of State Systems of Care
The advent of Medicare and especially Medicaid thus changed the face of mental health care dramatically. After World War II, mental health care was dominated by the state hospitals and thus by the states. Within the next generation, this change was spectacular. By about 1970, there were more episodes of psychiatric care in general hospitals than in state hospitals, and at about this time, the number of long-term mentally ill individuals in nursing homes became greater than the number of these patients in the state hospitals. Both of these trends were due more to the financing incentives in Medicaid than to the community mental health movement and the CMHCs. Both the CMHC legislation and Medicaid had undercut the SMHAs by providing funding streams that bypassed these agencies. The CMHC grants went directly to local providers with limited SMHA influence, and Medicaid was administered by a designated state agency (usually the welfare department, given its locus as a program for the poor). In addition, both programs provided funds to private for-profit and not-for-profit entities rather than to the public sector. This eventually created powerful; alternative provider forces in mental health to counter whatever political power rested with the SMHAs. The states had also lost potency because their major focus had been to run the discredited state hospitals; they were essentially cut out of the new mental health business in CMHCs and Medicaid-financed services. This change toward community-based care and the accompanying challenges are described in Table 86–4.
Treatments

had been created, serving a broader public and providing increased access to care. Private health insurance coverage had become much more prevalent. Whereas coverage for mental illnesses was generally far more limited than that for physical illnesses (both because of the stigma associated with mental illness and perhaps even more significantly because the state hospitals still existed as a catastrophic care option), private coverage helped expand mental health care dramatically. Access to mental health care had simply exploded, and the expansion took place in new settings. Figure 86–1 illustrates how dramatically the system changed.

The most significant change involved a dramatic expansion of care (from 1.7 million episodes in 1955 to 6.9 million in 1975, just 20 years later). The expansion occurred most significantly in the outpatient arena, in which the number of care episodes exploded from around 400,000 to almost 5,000,000, a more than tenfold increase. However, because of expanded Medicaid, Medicare, and private insurance coverage, the volume of inpatient admissions also rose from around 1,300,000 in 1955 to more than 1,600,000 in 1975, during a period generally thought to be associated with deinstitutionalization. A new mental health “system” was in fact being created, and it looked different from the old system (i.e., the state hospitals). The state hospitals, after dominating the US mental health care for more than a century, were speedily replaced as the primary locus of care. Figure 86–2

Table 86–4

Challenges Faced by Systems of Care During the CMHC Reform Movement

- Patients from state hospitals not moved to independent living, but to nursing homes, boarding homes (transinstitutionalization)
- CMHCs not prepared for large numbers of patients with serious and persistent mental illness
- CMHCs had to provide intensive care for acute, less severely ill patients to be profitable
- Expansion of Medicaid led to expanded general psychiatric beds
- State lost authority/responsibility for patients with serious and persistent mental illness

The 1970s: Increased Complexity, Expanded Services, Federal Indifference

By the mid-1970s, mental health care bore little resemblance to what had existed a generation before. Owing to the impact of Medicare and Medicaid, the new de facto publicly financed system was privately operated and largely outside the control of the states. The state hospitals were no longer the primary focus of either long-term or acute care. Nursing homes probably had more mental health long-term care beds than did state hospitals, although the data are not completely clear, and the number of psychiatric admissions to general hospitals was greater than to state hospitals. Hundreds of CMHCs

Figure 86–2 Episodes of mental health care by modality in the US from 1955 to 1975, showing the diminishing role of state hospitals. (Source: Witkin 1980 Trends in Patient Care Episodes in Mental Health Facilities, 1955–1975. NIMH Statistical note 156. National Institute of Mental Health, Rockville, MD, USA.)
illustrates this development. In the 20-year period from 1955 to 1975, the proportion of all episodes of mental health care that were provided by state hospitals (whether outpatient or inpatient care) shifted dramatically from half of all episodes to less than 10%.

State Hospitals Seen as the Problem
The conventional view of mental health policy evolution during this period ignored many of these developments. Because the state hospitals had become such a lightening rod for criticism by policymakers, partly because they had dominated the mental health landscape for so long that new developments were not apparent and partly, perhaps, because data on state hospitals were readily available when data on the new programs were not, the hospitals were still the focus of policy debates. When one examined the budgets of the SMHAs alone, the state hospitals were still a major category of expenditure. Data on the growing private sector system were not available on time, so analysis tended to focus on the state hospitals. Given that the responsibilities of the hospitals for care of patients had been dramatically reduced, their consumption of a significant percentage of all state resources seemed inappropriate. The national mental health leadership at NIMH and a growing number of articles in the professional literature reflected concern about the levels of resources tied up in the state hospitals, at a time when the balance of care had shifted to the community.

The reasons for inflated state hospital costs, noted in Table 86–5, did not seem so critical at the time given the imperative of community care, but they generally reflect developments outside the mental health field that were influencing costs. The unionization of public employees and the resultant wage increases and limited work weeks were a significant factor in increasing costs. In addition, the state hospitals had long relied on the labor of patients. This practice had evolved from a belief in the curative role of work to a managerial “necessity” to operate under-financed, custodial institutions. It was effectively curtailed by a Supreme Court decision (Souder v. Brennan 1973), with the result that hired staff were needed to replace the essentially free labor of patients. These external factors increased hospital costs. At the same time, increased governmental regulation designed to redress poor quality of care increased costs of the institutions. These factors, whether legitimate or not, contributed to the reformers’ demands to reduce the hospitals and to continue expansion of community mental health services. In a word, the policy preference was for deinstitutionalization. That adequate community supports for the most disabled were not being put in place was not yet apparent.

### Table 86–5 Reasons for Increasing Costs of State Hospitals

- Unionization of public employees
- Resultant wage increases
- Loss of “free” patient labor (paid staff had to be hired)
- Increased governmental regulation

At the same time, the national mental health “movement” was starting to run into problems. President Nixon was no friend of the NIMH. This may have related to his distaste for the social psychiatry approach of the NIMH leadership. NIMH Director Yolken had opposed Nixon’s tough drug sentencing policies, advocating a treatment approach (Rumer 1978). In any event, Nixon fought the community mental health program through the budget process. After proposing lower funding levels in 1971, Nixon actually impounded CMHC funds in 1973 after Congress had appropriated them. As a result, the CMHC program started to slip from its original goal of 1500 centers. From 1965 to 1969, 75% of the $260 million authorized for CMHC construction was actually appropriated. From 1970 to 1973, only 15% of the $340 million authorized was actually budgeted (Bloom 1975).

Emerging Conflicts in Mental Health Policy
The last half of the 1970s was thus a difficult and transitional period in mental health policy. Dramatic expansions of care had been achieved, with little positive impact on the most seriously mentally ill persons. The state hospitals were discredited, but no viable alternatives were widely available. Nursing homes had become the primary, largely invisible, locus of long-term care—along with other welfare-financed alternatives such as boarding homes. The CMHC and Medicaid programs had dramatically expanded access to care, but not for the most seriously mentally ill and largely outside the influence of the state governments that were responsible for the state hospitals. Given these trends, it is little surprise that a crescendo of criticism began to develop. The 1977 audit report by the General Accounting Office (Returning the Mentally Disabled to the Community, Government Needs to Do More) typified the new criticism.

President Carter, assuming office in 1976, was clearly more sympathetic to mental health concerns, and First Lady Rosalynn Carter made mental health her primary concern. The President’s Commission on Mental Health was established in 1977 to review the nation’s issues in mental health. Its 1978 report was perhaps even broader than the Action for Mental Health report published almost 20 years previously, in part because the system was much more complex and partly because the political tensions associated with new constituencies like CMHC directors made consensus much more difficult. As Mechanic (1989) has pointed out, the report was also produced in a national political environment that had changed dramatically. There was much less certainty about the appropriate role of the federal government and many more competing budget demands. The process of developing legislation based on the report was also correspondingly more difficult.

Two major activities resulted. The first did not have a happy ending. The 1980 Mental Health Systems Act was designed to build on but also redirect the CMHC program by focusing more on seriously mentally ill persons, connecting the program with state government, and emphasizing systems of care rather than facilities. President Reagan, taking office within months after the legislation was signed, proceeded to ignore and dismantle the legislation, in large measure by the conversion of the grant program to a block grant at reduced funding levels. The other major outcome of the President’s Commission was less visible but eventually influential. The Department of Health and Human Services had been charged with developing a more integrated federal approach to the problems of the most seriously mentally
ill individuals. Its 1980 report, as described by Mechanic (1989) “reemphasized the critical importance of Medicaid, Social Security Disability Insurance, and many other federal programs, and presented an incremental approach to modifying them in a constructive way.”

Many of the initiatives recommended in this report were also attacked by the Reagan administration. The most notable was the effort, eventually overturned in federal courts after intervention by legal advocates, to drop many seriously mentally ill individuals from disability insurance during the early 1980s. However, many recommendations survived this assault and were actually implemented during the same period that the Mental Health Systems Act was dismantled (Koyanagi and Goldman 1991).

Thus, whereas the momentum for federal leadership in mental health stalled with President Reagan’s shelving of the Mental Health Systems Act, federal programs quietly became more relevant and helpful to seriously mentally ill individuals during the 1980s—after the debacle related to disability insurance payments was resolved. The improvements included better disability insurance coverage, targeted attention to the mentally ill homeless, and particularly the development of Medicaid programs focused on community treatment for seriously mentally ill individuals. These programs, including case management and rehabilitation options, were used by many states to expand services during the last half of the decade. However, federal leadership was also significant during the decade, an irony given the budget cuts and retrenchment of the Reagan years. The small Community Support Program (CSP) in the NIMH exercised tremendous influence on the state mental health programs through national working conferences and a focused program of planning grants and demonstration grants directed to the states. During the 1980s, the states began to recover from the federal neglect of the prior decade and take advantage of Medicaid funding and CSP ideas to retool their community care systems. The federal improvements are highlighted in Table 86-6.

### The 1980s: Community Support and the Precursors of Health Care Reform

The state mental health programs had fared poorly during the prior 2 decades. The SMHAs were discredited as the operators of state hospitals, defined by community mental health advocates as the enemies of progress. In addition, the new CMHC and Medicaid initiatives of the 1960s had bypassed the SMHAs. A new mental health “nonsystem” dominated by nursing and boarding homes as well as general hospital psychiatry—all outside the effective control of the SMHAs—was now larger in scope than the programs controlled by the state agencies. Even the CMHCs, once thought of as a treatment alternative to hospitals but serving instead an entirely new group of patients, were under limited SMHA control. As the problems of this chaotic system became apparent—symbolized by the plight of the homeless mentally ill and punctuated by mass media coverage of periodic violent episodes involving mentally ill individuals—the states were the obvious target for criticism. The subtleties of the new “system” were not important in the face of these problems. The states ran the hospitals, let people out of them, and should have been doing a better job.

The changes of the 1980s allowed the states to regroup and recover from the feverish pitch of change. Although the Reagan new federalism approach had resulted in funding cuts, it had restored state control. For example, in the 1980 Reagan budget, the CMHC direct grants to centers were consolidated into a block grant, reduced by about 35%, and placed under state authority. In general, the states used these funds to focus on seriously mentally ill adults and children, using the new CSP model.

The impact of the CSP approach is difficult to overstate. Growing out of the Carter commission, it involved a focused approach to the multifaceted needs of seriously mentally ill individuals in communities. As Morrissey and Goldman (1984) have pointed out, this “fourth era of reform” differed in a fundamental way from the moral treatment, mental hygiene, and community mental health concepts. For the first time, serious mental illness was not conceived of as a fundamentally acute problem but was defined as a long-term and episodic condition requiring multifaceted supports. As a consequence, the service approach was not focused on a particular institution (e.g., the asylum, psychopathic hospital, or mental health center). Rather, consistent with the concepts of President Carter’s legislation, a multimodal system of care was necessary, incorporating both treatment services and the practical supports (such as housing, income supports) needed by people with disabilities as well as illness.

The CSP approach defined a number of essential elements of such a system which have been included in Table 86–7.

</table>

These concepts were promoted by the small CSP unit within the NIMH in a fervent, focused manner. The combination of small state planning grants (carefully defined to promote change) and demonstration projects was linked to the national CSP meetings in an effective change strategy. There were several remarkable things about the effort. First, the notion of aggressive federal leadership during the Reagan years is something of an anomaly. Probably, the program was too small—and perhaps too effectively protected by Congress—to have been a serious target. Second, the funding levels involved were completely insignificant compared with the hundreds of millions spent on CMHCs or the billions involved in Medicaid. The annual CSP appropriations were in the range of $10 million for the entire program. However, the funds were effectively used to “leverage” other resources, including state budgets, block grant funds, and the new Medicaid programs. The change in SMHA budget portfolios during the 1980s is the clearest example as illustrated in Figure 86–3.

During this decade, the SMHA budgets were essentially level when viewed in constant dollars. In other words, budget increases were essentially equal to inflation. Yet, during the decade, there was a steady shift in investments from state hospitals to community programs. The new community resources were often used to “match” Medicaid dollars and linked with block grant revenues and local funds. As a result, there was a dramatic expansion of CSP-type services that is not apparent from examining SMHA budgets alone. Unfortunately, there are few reliable national data that demonstrate the magnitude of this shift. The best way to get a view of the evolution of services for seriously mentally ill individuals in recent years is to track the development of systems at the state level, for which more complete data are available.

A Case Example of State Mental Health Policy and Funding

Understanding the changes nationwide in the shape of public mental health systems during the 1980s is made difficult because of the limits of available national data. Reliable national data are available on the budgets of the SMHAs, but the Koyanagi and Goldman (1991) analysis makes it clear that federal financing changes during the 1980s (such as the case management benefit in Medicaid) were also significant. However, these changes, unlike the CMHC effort of the prior decades, were not reflected in the categorical budget of NIMH. Rather, a multitude of federal programs were adjusted incrementally during the decade on the basis of recommendations of the 1980 Department of Health and Human Services report and the President’s Commission. Because many of these programs (e.g., Medicaid) were not dedicated primarily to mental health, tracking their impact is more difficult, and the changes have not been well recorded or understood. The changes cannot be appreciated by evaluating trends in the cumulative SMHA budgets, because many of the federal revenues flow through other agencies at the state level. Medicaid, for example, is often administered by human service or welfare agencies.

One way to see the impact of the change, and to end this historical review with a picture of the current public mental health system, is to examine the cumulative impact of federal, state, and local changes in a particular state—in this case, Ohio. An argument can be made that Ohio is appropriate for such analysis. Larger in population (seventh among the states in 1994) and smaller in land area (35th) than the average state, Ohio has a mix of urban and rural counties, spanning the range of communities that exist across the country. Its 1990 SMHA budget was $41 per capita, and 59% was spent on state hospital care, compared with the median SMHA expenditure of $38 per capita with an average of 59% spent on hospital care (Lutterman et al. 1993). Therefore, the overall levels and investment patterns of Ohio’s SMHA budget are close to national norms. A beginning point to trace the evolution of this system is to evaluate trends in the SMHA budget to determine the pace of movement from hospitals to community services. Figure 86-4 illustrates these trends and Ohio’s SMHA budget trends from 1987 to 1993. As illustrated, Ohio made substantial shifts from hospital to community support services during this period. However, the data on state budget expenses alone underestimate the dynamics of change during this period. Figure 86–5 includes not just the SMHA budget but all revenues used to support community mental health services delivered through the public mental health system in Ohio.
Figure 86–5 combines all sources of revenue received by the county-based mental health boards that are responsible for community mental health care in Ohio. The shift in investments to community support services is greater when these additional fund sources—principally Medicaid, local taxes, and federal block grants—are added into the picture. It illustrates how examining SMHA funding alone leaves an incomplete picture of mental health investments.

Federal changes reflecting the paradoxical combination of budget cuts (e.g., block grants) and the simultaneously more effective financing by Medicaid of community mental health care began to have a significant impact. For example, state hospital costs were 58% of the Ohio general fund mental health budget in 1990, but only 37% when all revenues are considered. Similarly, community mental health services funding increased to 121% from 1987 to 1993 when all funding sources are considered.

The state-level reform in Ohio, although perhaps broader and more aggressive than changes in many other states, does illustrate how the mantle of leadership in the public mental health sector shifted back to the SMHAs during the late 1980s. After the dramatic federal changes of the prior two decades, the states needed to consolidate their efforts. A primary vehicle for this effort in Ohio was the 1988 Mental Health Act. This legislation made services for the most seriously mentally ill the highest priority, required local (county-based or multicounty) systems to develop a community support program, empowered the boards as local mental health authorities, and gradually turned control of state hospital funds over to the local boards.

This step removed the historic and unintended incentive to institutionalize the most needy patients at state expense. The counties were now responsible for the costs of state hospital care on the one hand, but they could also choose to invest in community support services. This state reform legislation therefore followed but extended the themes of the ill-fated 1980 federal Mental Health Systems Act, just as the earlier Ohio legislation establishing the mental health boards in 1968 had followed the 1963 Community Mental Health Centers Act at the federal level. The reforms in Medicaid, which made it more useful as an additional funding source for community support services, added to the value of increased or reallocated state and local funds. There was thus a synergy among federal, state, and local initiatives.

The impact of the 1988 legislation, which followed a period of community program development and capacity building, was extraordinary. The most immediate and obvious impact was the community placement of long-stay disabled patients in a variety of housing arrangements, supported generally by case managers as well as by medication management and day treatment programs. Figure 86–6 shows the reduction in state hospital use in Ohio since this legislation. As illustrated, the reduction in hospital use was
Ohio data also reveal substantial changes in patterns of community care during this period. At a gross level, the number of individuals identified as “severely mentally disabled” (SMD) who were served increased, as did the units of service provided to the average SMD individual. However, there was a slight decrease in the number of non-SMD persons served and a decrease in the units of services provided to these individuals. Table 86–8 illustrates these trends.

Changes were also evident in the pattern of services received by SMD persons. Roth et al. (1995) used cluster analysis methods to trace how patterns of care for SMD persons evolved in time and how these related to outcomes. This research revealed that certain patterns of care were relatively stable for a period of time; a consistent 10% of all enrolled SMD persons received substantial levels of various services (labeled custom care by Roth et al. 1995), whereas nearly half of all enrolled SMD persons received low levels of service (about a single formal mental health treatment episode per month). On the other hand, in the 4-year period from 1989 to 1993, there was a significant change in the numbers of SMD persons being served through medication checks without other services. This pattern of care was provided to 23% of individuals in 1989, but this percentage declined to less than 10% by 1993. The apparent shift in this pattern was related to an increase in the use of case management and other services in addition to medical services, reflecting a more comprehensive approach to meeting the treatment needs of these persons. Table 86–9 illustrates these trends.

Ohio data also reveal substantial changes in patterns of community care during this period. At a gross level, the number of individuals identified as “severely mentally disabled” (SMD) who were served increased, as did the units of service provided to the average SMD individual. However, there was a slight decrease in the number of non-SMD persons served and a decrease in the units of services provided to these individuals. Table 86–8 illustrates these trends.

Changes were also evident in the pattern of services received by SMD persons. Roth et al. (1995) used cluster analysis methods to trace how patterns of care for SMD persons evolved in time and how these related to outcomes. This research revealed that certain patterns of care were relatively stable for a period of time; a consistent 10% of all enrolled SMD persons received substantial levels of various services (labeled custom care by Roth et al. 1995), whereas nearly half of all enrolled SMD persons received low levels of service (about a single formal mental health treatment episode per month). On the other hand, in the 4-year period from 1989 to 1993, there was a significant change in the numbers of SMD persons being served through medication checks without other services. This pattern of care was provided to 23% of individuals in 1989, but this percentage declined to less than 10% by 1993. The apparent shift in this pattern was related to an increase in the use of case management and other services in addition to medical services, reflecting a more comprehensive approach to meeting the treatment needs of these persons. Table 86–9 illustrates these trends.

Roth et al. (1995) also found that outcomes (reduced symptoms and better quality of life) improved overall for SMD consumers during this period. Thus, there is some empirical validation of both the community support

![Figure 86–6 Ohio state hospital census, by type, for FYs 1988 to 1994. (Source: Ohio Department of Mental Health 1995 Columbus, OH, USA. [Unpublished data])](image-url)
approach and the reform movement in Ohio during this time. This is not to say that the reform was an unmitigated success. Although community outcomes were positive and the quality of state hospital care improved (as measured by a 72% decline in the frequency of Medicare quality deficiencies from 1991 to 1994), there was conflict in Ohio about funding levels, the pace of change, and the future employment prospects of state hospital staff (Hogan 1992). In addition, the data on reduced levels of non-SMD services reflect a tension between the appropriate goal of increased services for the historically neglected population of seriously mentally ill persons and the unfortunate side effects—given limited public funds—of reduced services to other clients of the public system. However, the Ohio experience does demonstrate that reform in large public mental health systems is possible, and it illustrates the possibilities and dynamics of change in these systems.

The 1990s: Restoring Focus, Effective Treatments, Defective Funding, Executive Branch Attention

Restoring Focus: Public Mental Health Systems in the 1990s

The forces converging to change public mental health policy during the 1980s were thus subtler than the “top down” change processes of the mental health establishment during the prior two decades. Whereas the CMHCs are widely thought to have failed the test of serving those with serious mental illness, these organizations formed an essential community infrastructure that survived the dismantling of the federal program in 1980. Thus, many CMHCs became essential elements of the new community support systems that evolved during the 1980s. The new public system is funded through a complex blend of SMHA resources, Medicaid, and local funds. Although consistent national data are not available to document these changes, Ohio data presented in Table 86–8 illustrates how service emphases shifted. From 1989 to 1992, the total volume of services to adults classified as SMD increased to 71% in Ohio; units of services to other adults declined 22%. Similarly, the number of SMD persons served increased to 34% during this period, and the number of service units per SMD person increased to 27%. By comparison, the number of units of service for non-SMD persons decreased by 12%. Through the 1990s these trends continued. CSP services, targeted at adults with SMD and children with severe emotional disturbances (SED), increased as a portion of the Ohio Public Mental Health system spending from 8.17% in fiscal year (FY) 1990 to 16.2% in FY 1997 (Report of Ohio’s Mental Health Commission 2001). This data, in graphic form is presented in Figure 86–7. Clearly, the community mental health system was changing its priorities as it was expanding. The locus of care continued its hospital-based to community-based shift in the 1990s. In 1955, the percentage of patient care episodes occurring in 24-hour hospital care settings was 77%. This dropped to 42% in 1971 and declined further to 24% in 1997 (Manderscheid et al. 2000). On a smaller scale, Ohio Public Mental Health System spending on inpatient care decreased from 46.7% in FY 1990 to 25.4% in FY 1997. (See Figure 86–7) (Report of Ohio’s Mental Health Commission 2001). A focus on persons with more serious mental illness and relocation of this care in the community—which had been lacking in the 1960s reforms at both the national and state levels—had been restored.

Effective Treatments and Defective Funding

Coincident with this refocusing on the care of the severely mentally ill (SMI) in the 1990s, psychiatry reemphasized its expertise in treating biologically based diseases of the brain. Congress declared the 1990s “the Decade of the Brain” (Surgeon General 1999). New antipsychotics beginning with clozapine in 1989, followed by risperidone, olanzapine, quetiapine, and ziprasidone offered promise to individuals with schizophrenia unresponsive to or unable to tolerate earlier medications. Additional medications in the class of selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, provided new therapies for people with mood

1. Implementation of the Mental Health Act has changed funding priorities and redirected state hospital resources to community care, and fundamentally changed the mix of community services.

For example:

- Savings from Ohio Department of Mental Health hospital downsizing and restructuring have led to increased funding for community services, and the mix of community services now emphasizes community support and other services for SED/SMD persons. (Graphs 1 and 2)
and anxiety disorders. Indeed, depression treatment rates increased substantially from 0.73 per 100 persons in 1987 to 2.33 in 1997 (Olfson et al. 2002). Research supporting the usefulness, including the cost effectiveness of psychotherapies for a broad variety of mental disorders emerged (Gabbard et al. 1997). Studies show the effectiveness of other psychosocial interventions such as assertive community treatment, supported employment, family psychoeducation, integrated substance abuse treatment, and illness self-management techniques (Drake et al. 2001). While psychotherapies, other psychosocial interventions and pharmacologic treatments all offer promise in treating a wide range of mental illness there was a shift for at least some individuals receiving only treatment with medication. These developments helped bolster calls from advocacy and some individuals receiving only treatment with medication. These efforts at cost control are covered in detail in the later section on Economics in Mental Health.

Results of two recent multicenter studies, one in the US and one in the UK (Jones et al. 2006), comparing the outcomes of people with schizophrenia treated with the newer, more expensive antipsychotic agents to older, less costly medications has dampened some of the early enthusiasm for the newer drugs and called into question the assumption of their greater effectiveness especially compared with the substantially higher cost of these medications. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) and Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CULtLASS) antipsychotic studies have highlighted an ongoing area of research and debate in mental health care, that is the cost and effectiveness of mental health treatments and the balancing of these issues. Since it is often difficult to predict and access all the costs of a particular treatment as well do the type of long-term studies comparing various treatments and treatment combinations, the cost effectiveness of a specific treatment approach may take many years to establish. Additionally refinements in the diagnostic subtyping of study subjects may define a population for whom a treatment or treatment combination is more effective than others. For instance, British researchers (Simon et al. 2006) recommended first line combination antidepressant and psychotherapy targeted at individuals with severe depression. Compounding the cost effectiveness question for psychiatric disorders are funding streams which pay from nonclinical but effective interventions such as specialized vocational services. Finally, the issue of cost effectiveness of psychiatric treatment often is related to the potential cost offset for general medical care. However, Strum (2001) asserts that attempts to increase mental health expenditures by policies which promote increased access and utilization of behavioral health care will not be offset by reduction in general medical spending. He does acknowledge that for specific populations (usually those with high rates of general medical care utilization) targeted psychiatric intervention may decrease cost and/or improve clinical outcomes.

**Executive Branch Attention**

In the context of the struggle between calls to enhance services and calls to control costs, the executive branch of government drew attention to mental health several times in the 1990s. Although the early efforts at more sweeping health care reform during the Clinton administration failed, a few initiatives limited to mental health merit comment. In September 1997, the Office of the Surgeon General under Surgeon General David Satcher, M.D., Ph.D. authorized the initiation of a Report on Mental Health. The report, released in December 1999 drew national attention to mental health problems, noting:

1. “mental health is fundamental to health,”
2. “mental disorders are real health conditions,”
3. the “efficacy of mental health treatments,”
4. the “range of treatments for most mental disorders,”
5. the public are encouraged to seek help for mental health problems,
6. the special needs of specific populations including children and the elderly,
7. the contributions of the advocacy movements,
8. the systems issues of financing complexity, fragmentation of services and access to care.

A supplement highlighted culture, race, and ethnicity (Surgeon General 2001). In July 1999, a Call to Action to Prevent Suicide was issued (Surgeon General 1999).

The Clinton White House held a conference on mental health in 1999 to help decrease stigma and increase awareness of mental health issues (Surgeon General 1999). On June 7, 1999, President Clinton directed the Office of Personnel Management (OPM) to achieve parity for mental health and substance abuse coverage for federal workers by 2001 (OPM News Release 1999). President Clinton believed the federal employees program could serve as a model for other employers and the insurance industry (OPM News Release 1999). Results of this experiment in parity are reported in detail later in the Benefit limits section but in brief there was no significant increase in overall plan spending for either adults or children. (Goldman et al. 2006, Azrin et al. 2007).

**The 2000s: Spotlight Shining, Financing Friction, Public Health, and Prevention**

President George Bush kept mental health issues in the spotlight with his announcement on April 29, 2002, of the formation of the New Freedom Commission on Mental Health (White House Press Release 2002). The Commission’s report identified recovery as the overarching goal of a transformed system (President’s New Freedom Commission on Mental Health 2003). To achieve this goal the following component goals were described:

1. Americans understand that mental health is essential to overall health.
2. Mental health care is consumer and family driven.
3. Disparities in mental health services are eliminated.
4. Early mental health screening, assessment, and referral to services are common practice.
5. Excellent mental health care is delivered and research is accelerated.
6. Technology is used to access mental health care and information.
The report recognizes that to fully realize the potential of treatment and recovery services coordination of clinical care, maximizing the use of multiple funding streams, implementing new technologies in the fiscal, informational, and clinical realms and grappling with inadequate and unequal funding for access to mental health services is necessary. How this recent executive branch attention to and efforts at reforming mental health will be integrated into overall mental health policy remains to be seen. The hurdles to improved mental health care are more challenging as they no longer involve finding the most effective medication or psychotherapeutic treatments to help individuals recover but restructuring systems of care.

**Financing Friction**

The complexity of mental health funding has made it difficult to predict all the outcomes of shifts in payment and at times even difficult to collect uniform data regarding finances. While the headlines in the 1980s and 1990s about Medicaid funding were the increase in federal and state dollars spent at the local community level as well as lack of federal dollars available to SMHA's especially at state hospitals, the 1990s and 2000s brought different concerns. Meeting the state portion of the Medicaid match increasingly strained state and local budgets. In addition through a variety of mechanisms an increasing amount of federal Medicaid dollars were being tapped by states. SMHA's facing budget constraints within their own system increasingly looked towards these strategies which included coverage for inpatient services for Medicaid eligible people over 65 in an IMD facility, coverage for nursing facility services for Medicaid eligible people 65 and over in an IMD, coverage for inpatient hospital care for Medicaid eligible people under age 21 in an IMD, paying for IMD services through savings gleaned from Medicaid managed care, programs to incorporate state and county psychiatric hospitals into BHO's which contract with the state's Medicaid program by obtaining IMD expenditure authority through an 1115 Medicaid waiver, use of disproportionate share hospital (DSH) payments to state and county hospitals to offset the costs of caring for large numbers of indigent patients, and obtaining reimbursement for the costs to administer Medicaid programs. The increased use of these strategies did result in some changes designed to limit federal payments back to the states. The extent to which states used these options varied widely and data is somewhat difficult to collect. A state study covering years 2000 and 2003 estimated the Medicaid non-DSH funds as a percentage of total state hospital funding as ranging from 3% in Arkansas and California to a high of 30% in Iowa. Extrapolating these state estimates and other data the total contributions of Medicaid funds toward public hospitals (incorporating DSH funds with non-DSH funds of 29% and 5% respectively) total approximately one-third of public psychiatric hospitals total operating costs in 2001 (Draper et al. 2003).

In Ohio the straining of government budgets at all levels layered on top of the complexity of funding and policy strategies ultimately resulted in the same trends in services and resources noted earlier and captured in Figures 86–4 and 86–5. First SMHA spending on state hospitals care continued to decrease relative to spending on community services with community services spending surpassing hospital spending in 1996 (Figure 86–8). Second, when all revenues received by county-based mental health boards are considered the amplification of the shift in funding from hospitals to community services continued. Community funding more than doubled and state hospital funding remained essentially unchanged which given increases in operating costs actually represented a decline in funding. These changes are summarized in Figure 86–9.

**Public Health and Prevention**

Public health in general and public mental health in particular are often neglected in the US health care system with its emphasis on the treatment of individuals and individualized treatment. The US in the 2000s experienced several landmark events which in addition to the Surgeon General and Presidential reports focused additional interest in the area of prevention, detection and treatment of mental disorders. The terrorist attacks in September 2001, the subsequent war in the Middle East with increasing numbers of returning veterans experiencing PTSD and traumatic brain injuries and the Gulf Coast Hurricanes in 2005 with both the effects of the immediate trauma and the longer term issues of displacement and loss drew attention to the impact of mental disorders on both the individual and community.

These mass casualty events captured the attention of the country, especially in the treatment of trauma but also other types of mental illness. During this time there has also been renewed interest in the prevention of mental health problems by attempting to decrease exposure to or intervene early with children and adolescents who are exposed to much more common trauma such as abuse and violence in neighborhoods and schools. Efforts to prevent and increase treatment of drug and alcohol abuse have also been key strategies of federal, state, and local government agencies. Increased effort in the detection and treatment of mental disorders especially in primary care settings has also occurred. Much of this has been fueled by the cost off-set to private insurers or public payors achieved by identifying and treating illness such as depression in high users of general medical services. However, in addition to financial savings overall improvements in clinical outcomes have been demonstrated in multiple studies. Other projects have moved beyond early efforts focused on screening and detection to more sophisticated studies focused on care coordination and improving delivery systems using chronic disease management models (Kates and Mach 2007). A disease management model for depression at the Henry Ford Health System was able to show a decrease in suicide rate of 75% (Perfect Depression Program 2006).

A complementary public health issue emerging on the interface between general medical care and psychiatric care is the excess mortality and morbidity among people with serious mental illness (Miller et al. 2006). Issues raised include the contribution of substance use, including nicotine, rates of obesity, use of atypical antipsychotics, and access to care. Screening for medical illneses in psychiatric patients and developing models of treatment have been suggested as ways to decrease this problem.
Figure 86–8 Ohio state mental health spending from General Revenue Funds therefore continuing trends from state hospitals to community services between FYs 1993–2006. Ohio Department of Mental Health unpublished data 2007. *Beginning in FY 06, the department no longer collected Patient Fee data.

Figure 86–9 Funding in Ohio’s mental health system. All sources of revenue for community mental health care and state hospital inpatient revenue from GRF and Medicaid. Ohio Department of Mental Health unpublished data 2007
Implications for Mental Health Policy

The evolution of mental health policy in the US, outlined in Table 86–10, has thus produced a substantial public sector care system that is also exceedingly complex. Essentially consisting of state hospitals in the 19th century, the system expanded dramatically in the past generation by the community mental health, Supplemental Security Income and Social Security Disability Income, and Medicaid and Medicare initiatives of the 1960s. These efforts contributed to a substantial expansion of public mental health responsibilities but also to great blurring of boundaries and diffusion of these responsibilities. New privately provided but publicly financed alternatives such as nursing homes and general hospital psychiatric services were created outside the boundaries of the specialty “mental health system.” Income supports enabled some mentally ill persons to exist mostly on outside relief, such as welfare payments, but also weakened the boundaries of the traditional mental health system. The decade of the 1980s provided an opportunity for some consolidation and organization of this fragmentation. The community support concept provided a conceptual framework for understanding the changes that were needed in the new service system, recognizing its fragmentation on the one hand but focusing on the community survival requirements of people wrestling with the most serious mental illnesses.

As a result, in most states, the public mental health system is organized around some local entity, whether county government, special purpose boards or commissions, or provider organizations designated by the state to also manage a local system of care. These local systems exercise variable and incomplete control over the array of public supports that exist because the formation of alternatives is so complex and funded and regulated by so many governmental entities. Federal and state mental health grant resources are most likely to be coordinated at this local level. Increasingly, Medicaid-financed mental health care may be coordinated with the local care management system, but Medicaid remains a distinct government reimbursement program that may or may not be coordinated with state or local mental health authorities.

Programs in other human service areas that are relied on by individuals with serious mental illness (e.g., low-income housing, vocational rehabilitation, services for disabled students in higher education, mental health care within the criminal justice system) are probably not controlled by either the state or local mental health authority. However, the empowerment of local authorities has increased their ability to negotiate agreements and improve coordination with other systems. Yet this remains a serious challenge. Marmor and Gill (1989) have noted that meeting the needs of seriously mentally ill individuals is a particularly difficult challenge within the US political and governmental structure. Whereas good treatment and support require a high degree of coordination and “comprehensive” solutions, the US political system is oriented to incremental approaches, and there is a long-standing distrust of government-managed approaches. Therefore, the public mental health approach at the state and local levels remains a complex, open system.

As a remedial strategy for coping with system fragmentation and to aid individuals whose ability to plan and coordinate their own lives and services may be significantly affected by mental illness, most SMHAs and local mental health systems have adopted a case management strategy. Individuals or teams of case managers assume responsibility for guiding persons with serious mental illness through this maze and assisting them with personal planning. Case management programs as distinct entities are usually provided only to persons with more serious disabilities. For example, in the system approach described by Stein et al. (1990), a well-staffed multidisciplinary community treatment team (analogous to the clinical team and paraprofessionals who work together on an inpatient unit) is the core service for the most needy group of individuals in the Dane County, Wisconsin, system. For other persons receiving care in the publicly funded system, care coordination may be provided by their therapist.

In general, modern public mental health systems still function as a kind of safety net (or, in insurance terms, a “high-risk pool”) for the larger health and mental health system, providing care and support for the most needy, seriously mentally ill, and poor individuals in their community. Insurance-financed private care is now available to most Americans, but it is not available for long to those with the most disabling mental illnesses except in the most generous private plans. For these individuals, the public system is the safety net. Mental health is unique in health care with respect to this distinct care and financing system for those with the most serious illnesses. Despite the origins of care in the public sector and the still substantial role of public systems, the private sector—reimbursed by employer-financed insurance—has become dominant in mental health. Understanding the economics of reimbursement systems and their impact on care has thus become essential.

The Economics of Mental Health

Four interrelated types of financing, listed in Table 86–11, have developed to become critical elements of the economics of health care: out-of-pocket payments by individuals, individually owned or purchased insurance, employer-provided insurance, and government reimbursement. Each has different economic dynamics and affects mental health care in different ways. In general, the development of health care financing patterns in the US has followed this sequence, from individual out-of-pocket payments to government financing. At the same time, each of these patterns persists within the complex US “system” of financing health care. Additionally, in recent decades individually purchased insurance, employer provided insurance, and government funded plans have all been markedly affected by the increased prevalence of the managed care systems.
industry. A review of the evolution and dynamics of these financing approaches provides the best starting point for understanding the complex economic patterns of care.

### Out-of-Pocket Payment for Care

Before the development of insurance coverage, and indeed well into the 21st century, individual out-of-pocket payment for care was the dominant pattern in health care. This is the simplest and most direct form of financing: people pay for the services they use. There are, however, serious problems with this approach as a financing method for health care and especially for mental health care. The amount of care that any person may need—and thus the amount that must be spent—is unpredictable and may be more than the average citizen can afford when serious health problems arise.

In the case of mental illness, the onset of most serious conditions is often during early adulthood, the prime wage-earning years. By comparison, other health care costs tend to be highest in old age. The most serious mental illnesses also tend to be both long-term and disabling. Many individuals with the most serious mental illness are not able to work and are thus not in a position to pay for the costs of substantial care. Thus, individual out-of-pocket financing is not workable for these individuals. On the other hand, less serious conditions are frequently treatable by psychotherapy or medications. However, psychotherapy in particular and mental health care in general are highly price responsive, meaning that people will use less of it if they have to pay more. In fact, most people will use little mental health care—probably not enough for their good health—if they have to pay the entire cost. Taken together, these factors mean that out-of-pocket financing is a poor primary approach to financing mental health care.

The limit of out-of-pocket reimbursement, the dominant financing approach in the 19th century, provides the economic explanation of the need to create a public care system for people with the most intractable mental illnesses and explains the continuing role of the public sector as a kind of risk pool or safety net for the most needy. An economic explanation of the need to create a public care system for people with the most intractable mental illnesses also tends to be both long-term and disabling. Many individuals with the most serious mental illness are not able to work and are thus not in a position to pay for the costs of substantial care. Thus, individual out-of-pocket financing is not workable for these individuals. On the other hand, less serious conditions are frequently treatable by psychotherapy or medications. However, psychotherapy in particular and mental health care in general are highly price responsive, meaning that people will use less of it if they have to pay more. In fact, most people will use little mental health care—probably not enough for their good health—if they have to pay the entire cost. Taken together, these factors mean that out-of-pocket financing is a poor primary approach to financing mental health care.

The individual insurance approach does introduce the perception that “that could not happen to me.” This means that individual policies are less likely to provide adequate mental health coverage. If someone with an established illness were to seek to purchase individual coverage, the cost would be prohibitive because of the high risk the person presents. Therefore, the individual insurance approach also fails to provide adequate answers for mental health financing.

### Individual Private Insurance

In this simplest model of insurance, as Bodenheimer and Grumbach (1994) have described, a third party—the insurer—enters the health care relationship along with the patient and provider. This model was used in 19th century Europe, with guilds and businesses establishing voluntary benefit funds to which members contributed individually, which then provided aid when a member was ill.

The individual insurance approach does introduce the notion of spreading risk across a group of “covered lives,” thus shielding individuals from unlikely but extraordinary costs, because the risk of incurring these costs is shared by all members. Whereas this essential function of insurance is addressed by the individual insurance approach, this model has a built-in problem: the need to collect contributions and then administer payments for each member individually. This high administrative cost makes individual insurance difficult to sell and expensive to purchase. As a result, only a small percentage of the US population has individual health insurance. The principal sources of health coverage along with population percentage using them are shown in Table 86–12.

*Includes private insurance purchased with public funds.

Most of the economic dynamics associated with individual insurance are not different from those of out-of-pocket payment for mental health. Of course, insurance is now involved, and so decisions to purchase coverage as well as to use care are involved. This does have an impact on mental health; people are less likely, on average, to seek coverage for mental illness than for other health problems, perhaps because of the perception that “that could not happen to me.” This means that individual policies are less likely to provide adequate mental health coverage. If someone with an established illness were to seek to purchase individual coverage, the cost would be prohibitive because of the high risk the person presents. Therefore, the individual insurance approach also fails to provide adequate answers for mental health financing.

### Employer-Based Private Insurance

Bodenheimer and Grumbach (1994) have also provided a cogent analysis of the growth and dynamics of employer-based coverage, the dominant form of health insurance in the US today. The first such plan was developed at Baylor University Hospital in 1929, under an arrangement whereby the hospital agreed to provide up to 21 days of hospital care per person per year in return for a payment of $6 per person per year. This approach to financing care, with the provider also playing a role as insurer, became a dominant approach in the US. The hospital industry controlled development of Blue Cross plans, providing coverage initially for hospital services; state medical societies stimulated development of Blue Shield plans, which primarily covered physicians’ services. Starr (1982) has pointed out how this provider-dominated market acted to protect physicians and hospitals by ensuring a steady income and by keeping reimbursement generous. Cost control, on the other hand, was not a major priority.

Employer-based private health insurance became a dominant factor in the US health care as a side effect...
of seemingly unrelated policies: the wage and price controls imposed on companies during World War II. This policy constrained wage and salary increases but did not similarly limit fringe benefits such as insurance. Therefore, insurance coverage was an incentive for employees to join particular companies in a competitive labor market. After the war, unions began to negotiate for benefits, continuing the trend of expanded coverage. In addition, the favorable tax status of employer-paid benefits (because such benefits are by and large not counted as income for tax purposes) contributed to the growth in this type of coverage. As a result, the number of members in group health insurance plans increased from 12 million in 1940 to more than 100 million just 15 years later. Ever since that time, private, employer-financed group health insurance has been the dominant payment and financing mechanism in the US (Bodenheimer and Grumbach 1994).

The fit between employer-financed insurance and mental health care is not inherently a problem, as is the case with individual insurance or out-of-pocket payment. In this case, the adequacy of insurance depends on how the policy is priced and on the type of benefits. Unfortunately, pricing strategies and benefit limits have made the mental health coverage of many employer financed policies inadequate with employees paying a greater share of the cost.

Community Versus Experience Rating
In the early days of employer-financed coverage, the price of insurance was typically based on the health care use (and thus the cost) of the entire community. Segments of the population were not singled out for differential charges on the basis of their pattern of health care use. This “community rating” approach is consistent with the general purpose of insurance—to spread the costs or risks of costly and unpredictable events across a larger population. However, as insurers began to compete with each other for business, limiting prices became increasingly important, and the practice of “experience rating” developed: the strategy of pricing insurance on the basis of the actual health care use patterns of the insured population. This approach quickly proved to be a problem for individuals with mental illnesses or other substantial health problems, especially when coupled with other strategies used by employers or payers to limit their costs by controlling “risk” at the point when insurance is purchased. A principal approach to accomplish this is to deny coverage to individuals with expensive “preexisting conditions,” which has resulted in denial of coverage to many mentally ill persons.

Experience rating and denial of coverage to potentially expensive consumers (usually those for whom the insurance is most needed) are responses to the competition that has emerged in the private insurance market. By limiting costs through selection of a healthy population, insurers or self-insured employers can partially control their costs, albeit by using strategies that run counter to the basic insurance premise of spreading risk broadly. The other main strategies for controlling insurance costs all target the levels of care that is provided. An obvious first approach is to limit what treatments the policy will cover.

Benefit Limits
Despite the problems for mental health coverage associated with insurance pricing, benefit limits that discriminate against mental health care have probably been more of a problem. The presence of the public mental health system already created an indirect obstacle to broad mental health benefits, because care for catastrophic conditions was available to those without insurance in this separate system. The competitive pricing strategies of insurers acted to further limit growth in private, employer-financed mental health coverage. A range of coverage limits has been used to control insurance costs: deductibles and copayments (in which the consumer-patient pays a portion of costs before the insurer does) as well as caps on what the insurer will pay (per episode, per year, or in a lifetime). In addition, limits may be placed on what services will be reimbursed, and mental health has not fared well under this approach.

State-of-the-art care for mental illness involves early intervention with medication or psychotherapy. Hospital stays are used sparingly, and a wide variety of rehabilitation and other services are required for many individuals with schizophrenia and other serious disorders. In other words, a wide variety of services may be required and used in a tailored treatment approach over time. In general, benefit limits in mental health preempt almost all of these treatment strategies. Outpatient treatment has been a first target in many mental health plans, for several reasons: the prevailing stereotype that “talk therapy” goes on endlessly without result, and the fact that increases in outpatient therapy use have in fact raised costs substantially in generous plans. As discussed earlier, psychotherapy is in fact highly price responsive: if it is essentially free, people will use a lot of it (in comparison to other visits to physicians, which do not vary as much depending on the cost to the consumer). This high responsivity also makes mental health treatment very sensitive to benefit management.

On the basis of these factors, many insurance plans limited mental health outpatient therapy to a few visits and required a 50% copayment (compared with the typically unlimited visits available to other physicians, with 20% or smaller copayments). Whereas these limits effectively control expenditures in the short term, they create a disincentive for early treatment and thus contribute to higher rates of hospitalization, which costs more.

For the reason that the covering costs of necessary hospital care is a core function of insurance, eliminating psychiatric hospital coverage was generally seen as unacceptable, and most insurance policies provide generally equivalent hospital coverage for psychiatric and physical illness—to a point. Since repeated or long-term hospitalization can lead to extreme costs in serious mental illness during the life span, coverage limits have targeted long or repeated stays by annual or lifetime limits on the amount of care that would be paid. Using these patterns, in an attempt to reveal the impact of coverage limits on consumers, the New York Times concluded in 1989 that a person with schizophrenia could expect lifetime treatment costs of $294,800, with less than 25% covered by insurance. A patient with ischemic heart disease, by comparison, would face lifetime treatment costs of $108,350, with more than 90% covered by insurance. The dramatic expansion of high-technology care for such conditions means that the total medical costs for treating them is dramatically increasing.

A final area in which coverage limits are typically a problem in mental illness also relates to serious conditions
such as schizophrenia, for which flexible care including approaches such as ongoing case management, rehabilitation at partial hospital programs, and crisis care are used to minimize inpatient care. Many of these services are typically not covered in health plans because they appear to be “added expenses.” The ironic result is that extended or repeated hospitalization can result from inadequate community treatment, driving up costs to the insurer to the point of coverage limits, and then leaving the patient without coverage. Limits to coverage are thus a problem for patients, and unless the coverage limits are extreme, they tend to fail at cost control, because patients use up whatever coverage is available.

Mental health thus presents a paradox in terms of cost control. Outpatient care is more price responsive than comparable physical health care, and insurance costs will rise unacceptably unless these costs are somehow controlled. During the late 1980s, a period emerged when benefits became more comparable with other health costs, including a 27% increase from 1987 to 1988 (Employee Benefit Research Institute 1990). Yet controlling costs through arbitrary benefit limits does not work well. Too stringent limits on outpatient care and alternatives to hospitalization drive up hospital costs. It is evident that purely economic controls are not adequate to appropriately balance care and costs in mental health.

Recent data suggests that the effect of benefit limits may be overshadowed by the prevalence of managed care techniques which will be more fully explored later in the chapter. As noted earlier President Clinton in 1999 directed the Office of Personnel Management to ensure parity of mental health and substance abuse benefits for the Federal Employees Health Benefits (FEHB) Program. Full parity for these disorders was implemented in January 2001. The impact of parity for both the plans and the beneficiaries has been studied for adults (Goldman et al. 2006) and children (Azrin et al. 2007).

For adults, the study showed no significant increases in spending attributable to the implementation of parity (Goldman et al. 2006). Spending and rates of use did increase in the FEHB plans but also increased for the control plans. In most of the FEHB plans there was a significant reduction in out-of-pocket spending for beneficiaries. Analysis of the effect of parity for children in the FEHB program showed similar results. Although utilization and spending in both, the parity and control plans increased overall there was no additional increase in utilization and spending attributable to parity. Two of the seven parity plans experienced decreased spending the other plans showed no difference. Beneficiary out-of-pocket spending decreased significantly in three out of seven plans, in the other four spending decreased but was not significant. The conclusion in both studies was that parity could be adopted without the outcome of increased costs to the plan and with the benefit of decreased financial liability to plan users. However, they also conclude that parity alone did not improve access.

Trends and Approaches in Government Financing

Government financing of care (primarily through Medicare and Medicaid) has been a major force in the US since these programs were introduced in the 1960s. The general trends and dynamics of Medicare and Medicaid have already been discussed. However, these programs, especially Medicare, have also served as a laboratory for benefit design and other cost control approaches. As Bodenheimer and Grumbach (1994) pointed out, these programs have greatly expanded coverage and access to care for elderly, poor, and disabled Americans. At the same time, they aggravated the problem of rising costs and contributed to growing federal budget deficits.

Several innovations in paying for care under Medicare have helped to clarify the challenges of appropriate benefit design and payment for mental health care. These innovations were the use of diagnosis-related groups (DRGs) and the Resource-Based Relative Value Scale (RBRVS). Each of these approaches has significantly shaped thinking about reimbursement in the past several decades.

Diagnosis-Related Groups

The DRG payment methodology was introduced by Medicare in the 1970s as a means to control inpatient costs. The theory was to pay hospitals fairly for an episode of treatment by calculating the appropriate length of stay for treatment of a given illness or condition. Thus, norms for treatment length of stay were established for comparable diagnoses, and payments were made on a per-episode basis rather than by the traditional per diem method. The idea was that hospitals would be rewarded for efficient care by pocketing any savings associated with shorter lengths of stay; inefficient care would cost the hospital more than the DRG payment. Criticism of the approach was loudest from psychiatrists; concern that diagnosis was an inadequate predictor of treatment needs turned out to be correct. Evidence marshaled by the psychiatric community confirmed that diagnosis alone was a poor predictor of the length of stay for psychiatric illness. As a result, Medicare exempted psychiatric units from the DRG payment approach, used nearly universally across other areas of medicine.

The rejection of the DRG approach was initially seen as a victory for mental health treatment, because there was concern that the approach would have led to widespread “creaming” (selection of patients for treatment who in fact had limited needs) and “dumping” (failure to adequately treat needy patients). The rejection of the DRG approach was something of a political victory for the mental health field and particularly for the profession of psychiatry. However, there were also negative effects of the DRG exclusion. First, profit-oriented companies realized that mental health was a less regulated area of health care and rushed in to establish profit-making units, especially in southern states with less general regulation of health care. These units marketed their services heavily and generally paid incentives to staff to maximize the number of admissions. Adolescents with vague “behavior problems” were frequently the major group served in these units, and excessive and often inappropriate treatment stays were typical. These problems led to many investigations and congressional hearings. In some instances, the “milking” of benefits for inappropriate care was so excessive that it consumed patients’ insurance coverage up to lifetime limits, meaning that they would be unlikely to ever be able to afford private coverage. The rationale for excluding mental illnesses from DRGs also compounded an image problem for mental health treatment among payers, insurers, and legislators: the perception that psychiatric...
diagnosis is subjective and that treatment is both unpredictable and generally ineffective.

Although Medicare-financed inpatient psychiatric care remained excluded from DRGs, a number of states adopted variants of this approach to pay for inpatient psychiatric care under Medicaid. Ironically, these tailored approaches seemed to work reasonably well and to avoid the problems predicted for DRGs in mental health. An approach implemented in New Hampshire is among the best documented of these modified DRG strategies in Medicaid. Described by McGuire et al. (1990) the New Hampshire payment strategy considered the type of admission (scatter bed or psychiatric admission to a medical–surgical unit, admission to a distinct psychiatric unit, or involuntary admission to a specialized unit) and also provided for payment adjustments for “outliers.” This adjustment addressed the problem of particular cases for which a longer length of stay seemed justified by providing a reduced payment for extended care, at a level calculated to be low enough to discourage extended inpatient care but high enough to discourage premature discharge. These features, added to diagnostic groupings, seemed to address the problems predicted for mental health care under DRGs. Beginning January 1, 2005, a new Medicare DRG approach to psychiatric inpatient care was implemented.

**RBRVS**

Although a significant innovation in payment, DRGs addressed only inpatient care, and medicine in general was moving in the direction already set in mental health—more outpatient care and less hospitalization. (DRGs also failed to address other cost problems in medicine, such as competition to acquire expensive technology, and the problem of high costs associated with treatment during the last few months of life. However, these topics are beyond the scope of this discussion.) The RBRVS was Medicare’s effort to set a rational payment approach for outpatient physician care—a kind of DRG approach for funding clinic and office visits. Under this approach, the level of “resources” required for a given visit or treatment was studied and normed. Resources included the amount of time, level of training and expertise, and other factors that interacted with the particular condition under treatment to produce an acceptable level of care. Similar to the DRG approach, the RBRVS then adjusts payment levels to reflect these national norms.

There has been less controversy associated with the practice of psychiatry and the RBRVS approach than occurred with DRGs, partially because psychiatry was treated more like other forms of medicine in the outpatient area. If the approach had any particular significance, it was in the recognition that visits or interventions requiring high levels of “cognitive” training and expertise had traditionally been undervalued in payment schemes, compared with visits to surgeons in particular.

**The Tax Equity and Fiscal Responsibility Act (TEFRA) and the Balanced Budget Act**

Exemption from the DRG prospective payment system and inclusion in the RBRVS reimbursement scheme, which recognized cognitive versus procedurally dominant medical services generally enhanced resources for psychiatric services. The 1982 TEFRA reimbursed psychiatric services on a cost-based system per discharge, which included capital costs, bonuses for lower costs, and bad debt, explains Health Policy Alternatives 1998 (Garriston 1999). Under the TEFRA and earlier funding plans, private inpatient psychiatric services boomed in the 1980s. Redick et al. (Mechanic et al. 1998) note that between 1970 and 1992, specialized psychiatric units increased from 664 to 1516, the number of private mental hospitals more than tripled and admissions quadrupled. As noted earlier, some of this expansion resulted in inappropriate utilization of inpatient care but the greater overall effect was the vast expansion of the role that the private (albeit publicly funded) care system played in the provision of acute psychiatric care. Between 1988 and 1994, discharges for a primary psychiatric diagnoses from general hospitals increased approximately 35% from 1.4 to 1.9 million per year with the largest growth (53%) occurring in private nonprofit hospitals (Mechanic et al. 1998). At the same time public general hospitals experienced an approximately one-third reduction in the number of discharges from 132.1 to 83.8 million per year. The number of days of care in mental hospitals, excluded as “IMD” facilities from receiving Medicaid funds, declined overall with the largest decrease occurring in public hospitals (12.5 million days) and far exceeding the increase of 1.2 million in general hospitals (Mechanic et al. 1998). Additionally, the rate of discharges for severe mental illnesses (SMI) in general hospitals increased from 196 to 314 per 100,000 population with the largest increase (almost 90% higher) being found in private nonprofit hospitals. In these institutions 12% more of the total bed days were for patients with SMI. Mechanic also notes that proprietary hospitals had transfer rates higher than nonprofit hospitals with the differences being more pronounced for patients with SMI in general, and especially for patients with schizophrenia. As a result of an uneven distribution of caring for Medicaid enrollees and uncompensated care, Mechanic argues for identifying those institutions which are assuming the larger share of this burden and targeting them for public support in order for them to provide the public safety net.

In 1997, rather than this targeted support for general hospitals which were providing an ever increasing proportion of acute psychiatric care, including care for individuals with SMI, Congress enacted and President Clinton signed the Balanced Budget Act (BBA) of 1997. The Congressional Budget Office (CBO) estimated that the act would save $112 billion by slowing the growth of Medicare and $7 billion by changes to Medicaid over the 1998 to 2002 period (CBO 1997). A majority of the reduction in Medicare was to come from reduced payments to hospitals, according to Ramsey Wallace (Garriston 1999). Payments to physicians also were targeted for cuts. The Medicaid savings were to be achieved largely by reducing payment to disproportionate share hospitals (facilities that provide a high volume of services to the Medicaid population) (Garriston 1999). The Medicare Balanced Budget Refinement Act of 1999 restored slightly less than 10% of the funding cuts made in the 1997 legislation, increasing federal spending by 10.5 billion for the 2000 to 2004 period (CBO 1999).

These cuts in public funding for private hospital care has raised the concern that the closing of psychiatric units which began in the late 1980s and 1990s in the for-profit
The hospital bed and occupancy numbers point to a great shift in acute psychiatric care in the last 20 years. Most patients now receive inpatient care in private hospitals although their care is often publicly funded. Occupancy rates in these hospitals has risen steadily over the last decade. The number of beds and units available in the private facilities is controlled by the hospitals themselves with market forces often being a large factor in these decisions. After the initial tremendous increase in private psychiatric beds from the 1970s to 1990s, the number declined through the late 1990s and early 2000s both nationally and in Ohio. By the mid-2000s, national and Ohio state trends showed stabilization and even small increases in the numbers of beds.

In summary, payment reforms in Medicare, including both DRGs and the RBRVS, have had a significant impact on medicine and psychiatry without fundamentally solving the cost problems in the health care system. Psychiatric care, initially exempt from DRG payment schemes and benefiting to some extent from RBRVS payments has faced increased pressure along with the rest of medical services from implementation of the cost cutting Balancing Budget Act of 1997 which reduced Medicare and Medicaid reimbursements. Current levels of public funding of care within the private sector may not be enough to prevent erosion of this latest safety net for people with mental illnesses.

The impact of the earlier payment reforms (DRG and RBRVS) has extended beyond Medicare, already the largest single payer of health care bills in the US. Surveys of 24 Blue Cross and Blue Shield insurance plans in 1994 found that for physician payment, greater than three-fourth used the Medicare RBRVS approach and for hospital reimbursement, two-third used a DRG approach (Grading Health Care Reform 1994). Thus, systems that attempt to link standards for payment to the type of illness and condition have had a growing impact. Two major problems persist, however. First, these methods do not address other reasons for cost increases in health care. Second, these broad-brush strategies fail to address the normal and appropriate variances in care required by individuals. By using a “lowest common denominator” approach to payment, these methods do not capitalize well on either payer or physician ingenuity in treatment. However, these methods were implemented during a time when there was also active experimentation with these issues and with approaches that blend economics, clinical knowledge, and systems technology to achieve better service quality and cost control. Often labeled managed care, these

approaches have rapidly shaped health care in general and mental health care in particular.

The Emergence of Managed Care and Its Impact on Mental Health

It is clear that the evolution of health and mental health policy has involved a dynamic tension among social–political forces, clinical philosophies and practices, economics, and the organization of care systems. In the 19th century, mental health care was shaped more by social forces and related clinical philosophies, as in the connection between Jacksonian reform and the establishment of asylums. In the closing decades of the 20th century, economics has arguably been the dominant force shaping mental health.

There has been a dramatic expansion in the availability of care and the emergence of a substantial private sector of mental health treatment financed by employer-based private insurance. Yet old problems have persisted, and a new problem has become dominant—the costs of care. By the early 1990s, health care costs in the US were a higher proportion of the gross national product than in any other developed country, and the rate of health care cost inflation was among the world’s highest. Despite widespread attention to the costs of healthcare in the US the 2000s brought little change. The US spent $2.0 trillion in health care costs or $6,697 per person in 2005. Although the rate of rise appeared to be moderating in mid-decade, health spending represented 16.0% of the gross domestic product (GDP) in 2005 (CMS 2007). In seeking solutions to this problem, health care has sought new organizational forms involving arrangements such as health maintenance organizations (HMOs), individual practice associations, and preferred provider organizations. These approaches involve variously organized networks or associations of providers and move beyond strictly economic strategies that seek to alter costs by modified payments to providers or charges to consumers.

The Nature and Growth of Health Maintenance Organizations

HMOs are, fundamentally, group medical practices that are prepaid—the practice organization is paid a set amount by its members in advance to take care of them if they are ill or even, indirectly, to protect their health. The first prepaid group practice was in 1929, when two Los Angeles physicians contracted with employees of the Los Angeles County Department of Water and Power, and their families, to provide comprehensive health care services in return for prepaid fees (Bennett 1992). With the Great Depression, World War II, and the subsequent effort by both employers and health providers to develop insurance-financed care arrangements, fee-for-service arrangements were dominant, and cost control took a back seat. Although some notable HMOs such as Kaiser Permanente developed during this period, the majority of care was paid for by retrospective fee-for-service arrangements. HMOs were viewed as alternative medicine and resisted by most physicians and physicians’ groups. HMOs use a wide variety of means to provide care while controlling costs, including controlled staffing levels, salaried staff, “wellness” programs, and use of nurses and other clinical staff who are paid less than physicians.

Ironically, given their image as an alternative social innovation, HMOs received a major boost as a key ingredient in the Nixon administration’s health care reform proposals, with Paul Ellwood as the champion of the concept. Credited with coining the term health maintenance organization, Ellwood saw HMOs as a way to improve care while containing costs and made the approach a central element of Nixon’s proposals. The Health Maintenance Organization Act of 1973 was the result. This legislation subsidized the creation and expansion of HMOs and broadened the approach to allow profit-making corporations to become HMOs and to allow “medical care foundations” to function as HMOs (Bennett 1992). Medical care foundations evolved to be known today as independent practice associations, one of the major variants of prepaid plans. An independent practice association may be described as a “loose HMO,” in which a group of practitioners agree to accept fixed fees without formally organizing into a group practice. (In the HMO, by comparison, physicians are employees of the organization and are almost always salaried.)

Certain forms of cost containment are “built into” prepaid plans such as HMOs. The prepaid nature of services itself introduces an incentive to avoid providing unnecessary care. The apparent ability of HMOs and the other prepaid and managed care approaches to control costs is certainly a major factor in their expansion. In 1983, fewer than 14 million Americans were enrolled in HMOs (Goran 1992). By 1991, 47% of Americans with employer-financed health insurance were in managed care arrangements. By 1994, this figure had climbed to 65%, and HMOs claimed more than 50 million members (Eckholm 1994). The increase continued to over 75% of the insured population being in some type of managed care plan by 1998 (Frank and McGuire 2000).

Preferred Provider Organizations

Preferred provider organizations are another variant on the organization of health care, sharing some similarities with both HMOs and individual practice associations in terms of structure and approach. In the typical preferred provider organization, a group of physicians—who usually do not practice together but maintain their own offices—negotiate discounted rates with insurers in return for “preferred” status as the primary health care providers for the insured group. Thus, the preferred provider organization is not a prepaid arrangement, but payment to the group is based on discounted fee-for-service rates. As in the case of HMOs, members typically pay a penalty for getting care outside of the network. At a minimum, the copayments for care outside the network are higher. In some situations, the insurer will not reimburse at all for care outside the network, except in emergencies.

HMOs and Mental Health Care

The history and track record of HMOs in providing mental health care is unexceptional. In a way, it parallels the record of mental health care under private insurance in general: limited benefits, an emphasis on a few treatment approaches, and gradual evolution to more satisfactory patterns of care. However, some of the dynamics of HMOs affect mental health care in particular ways. The 1973 Health Maintenance Organization Act required that HMOs provide only a limited mental health benefit (crisis care and up to 20 sessions for evaluation and brief treatment, with no coverage required for inpatient care or for treatment
of ongoing conditions). Whereas many plans found that this low benefit level was unworkable and added coverage for inpatient treatment, the profile of psychiatric care in most HMOs remained low. Martinsons (1988) found that the common level of mental health expenditures in HMOs was 3−5%, contrasted with 8% of all expenditures in fee-for-service plans. Some observers now believe that mental health consumes on average up to 12−14% of expenditures in fee-for-service plans, raising serious questions about the adequacy of mental health service levels in HMOs.

Emergence of Managed Mental Health Care

Stimulated largely by the substantial increases in mental health expenditures during the 1980s and the failure of strictly economic approaches to control costs, managed care techniques were increasingly applied to mental health care. The primary strategies employed in early managed care efforts might best be described as “managed cost” attempts to intervene in treatment decisions like hospitalization to prevent all unnecessary expenditures. These arrangements typically involved the requirement that third-party reviewers (frequently entry-level clinical staff armed with procedure code-books) authorize any inpatient admissions. This authorization would usually cover a limited time, with the requirement that permission be obtained for any treatment beyond this initial period. The clear target of early managed care efforts was psychiatric inpatient treatment, which had been the area of greatest cost increases during the 1980s as benefits were expanded. These arrangements were successful in limiting costs but angered many psychiatrists.

The early managed care efforts did demonstrate the efficacy of a specialized approach to management of mental illness care, against the typical pattern of high costs in fee-for-service plans and low levels of services in many HMOs. Consequently, a “carve-out” strategy was increasingly used by employers, who would contract with a distinct entity to manage all mental health and substance abuse treatment needs of the covered population. Such arrangements, in addition to limiting treatment costs, started to demonstrate effectiveness in improving outcomes, such as improved access with increased number of people receiving behavioral health services and decreased medical costs (Cuffel et al. 1999).

As expertise in these practices grew, specialized managed care providers, during the late 1980s and early 1990s, moved beyond the crude managed cost efforts of the first-generation programs. The second tier of programs began to use more sophisticated approaches, including selecting their “network” of providers on the basis of reputation and credentials in addition to low cost, offering training in more effective or relevant treatment approaches, and initiating new but lower cost services rather than just denying access to care. For example, partial hospital programs and intensive outpatient services were developed to provide an alternative to inpatient treatment for some patients. Thus, these second-generation efforts focused on managing care as well as cost.

As distinct “behavioral managed care” programs evolved, efforts turned beyond screening—prior authorization methods and the selection of lower cost providers—and put more emphasis on quality assurance protocols that provided feedback to psychiatrists. This evolution has led to the third generation of specialized managed care. The program developed by IBM in the early 1990s provided a benchmark for these more sophisticated efforts.

Like other large employers, IBM had seen its mental health and substance abuse treatment costs rise dramatically under its fee-for-service insurance with generous benefits. The company was committed to cost control but equally insistent that this not be achieved through limiting benefits and crude rationing. In developing specifications for its new program, IBM employed an independent mental health advisory board to both assist in the development of a managed care program and oversee its operation.

The resultant program, operated by one of the new behavioral managed health care firms (American Psych Management), was designed to operate as a complete system responsible for screening needs, establishing a preferred provider network, managing care received through this network, and conducting extensive customer satisfaction and quality assurance monitoring (Bengen 1992). Within this program, more extensive benefits were offered than were available under the prior fee-for-service program (e.g., residential treatment centers and other residential care), but all services were subject to care management and individual treatment planning.

This type of arrangement is relatively typical of third-generation managed care programs, in which the functions of utilization review and care management, as well as responsibility for actually providing care, are assumed by the managed care firm. The firm employs mental health clinicians (supervised by psychiatrists) to conduct the care management function, recruits providers into a closed panel or network, and manages the care network including quality assurance functions. In these arrangements, the firm is essentially a specialized or carved out HMO, responsible only for mental health (and, typically, substance abuse care).

The basic concept of this approach is also remarkably similar to the design of the public sector CMHCs developed several decades earlier, although the managed care firm serves a covered population and the CMHC functions as a network of care for a primarily uninsured population.

Behavioral health carve-outs of benefit management alone or combined with the provision of care appear to have improved the quality of mental health care but integration of general medical and psychiatric care especially for people with co-morbid conditions is neither addressed nor improved by this approach.

Managed Mental Health Care in the Public Sector

By the early 1990s, managed care’s presence in employer-sponsored health insurance was well established and new markets were sought. At the same time, state governments concerned about increasing budget deficits and specifically about the ever growing proportion of state budgets spent on Medicaid, looked to managed care as a mechanism to control costs. Together, these factors resulted in a rapid expansion of managed care into both public general medical care and into public mental health care. Mechanic et al. (1998) reviewing HCFA data report that by 1997 nearly half of Medicaid recipients were enrolled in a managed care plan. Croze (2000) citing a Substance Abuse and Mental Health Services Administration (SAMHSA) 1998 report, states that 46 states were implementing managed mental or behavioral
health in some form and 10 states had virtually no fee for service behavioral health care funded by Medicaid. Of these 46 states, 25 handled a significant portion of their Medicaid benefits through risk arrangements in which risk is transferred from the state Medicaid agency to another entity. Seventeen states utilize a managed behavioral health care organization (MBHO) carve-out in some manner. The risk however is transferred to a variety of organizations including a MBHO, a MBHO/provider partnership, the county government itself or an authority appointed by county government, a CMHC or local behavioral health authority. She describes the complexities of these new arrangements, including common emphasis on “medical loss ratio” (maximum dollars directed to care and treatment), use of caps on profit and administration, frequent requirements for reinvestment in service development, financial reserves, and performance bonds and/or lines of credit.

Another common feature is the exclusion of pharmaceutical coverage within the behavioral health contract. This is a strategy recommended by the Department of Health and Human Services—Office of the Inspector General by HHS-016 as reported by Ross (2000) due to concern by states that they could not accurately determine the cost for this benefit and were concerned that if not costed correctly managed care organizations would restrict access. However, as pharmaceuticals (psychotropic and other drugs) account for a growing proportion of health care spending this exclusion may need to be reconsidered.

Between 1999 and 2000, spending on drugs in the US increased by 18.8% from $111.2 billion to $132 billion (Charatan 2001). Three factors accounted for most of the increase; a larger number of prescriptions, the use of more expensive drugs, and price increase (Charatan 2001). Aggressive marketing by drug companies also contributed to the spending increase (Charatan 2001). Newer antidepressants and antipsychotics are substantially higher priced than older medications. Together, these families of psychotropics account for a large proportion of the increase in spending on drugs. Antidepressants represented the second highest sales by class of medications in 2000 at $8.3 billion (IMS Health 2001). Antipsychotics ranked sixth in sales at $4 billion (IMS Health 2001). In 2000, the top ten list of the US sales of prescription products included two SSRIs and one new antipsychotic (IMS Health 2001). Antidepressants widely used across both general medical and psychiatric settings have a broader impact in prescription costs. Newer antipsychotics used primarily for the treatment of schizophrenia spectrum disorders disproportionately impact Medicaid spending. Medicaid spending on antipsychotics increased nearly 2.5 times between 1995 and 1998 from $484 million to $1.264 billion (Mulligan 2002).

Medicaid spending on prescriptions continues on an accelerating course. Between 1994 and 1998, Medicaid spending increased from $8.4 billion to $13.6 billion. The next five year period 1999 to 2003 showed an increase from $16.2 billion to $34.3 billion. Together, these represent a greater than four fold increase in spending over 10 years (Lied et al. 2006). For Medicaid, the increase in spending was due to the increased number of enrollees and an increase in the mean price per prescription (Lied et al. 2006). In 2003, Medicaid spent approximately $7.3 billion on central nervous system drugs (mostly for the treatment of psychiatric disorders), the highest single category of drug spending making up 21% of the total drug reimbursements (Lied et al. 2006). Indeed, in both 1998 and 2003, the antipsychotics Zyprexa and Risperdal held the first and second spots for total reimbursements (Lied et al. 2006). Both drugs experienced over 100% increases in the number of prescriptions during the time period (Lied et al. 2006). The large increase in Medicaid drug costs especially psychotropic costs have led to a variety of strategies by states to control these costs. New Hampshire’s attempt in 1981 to control Medicaid spending by limiting prescriptions to 3 per month resulted in savings in drug costs but this was negated by a even higher increase in mental health costs including outpatient visits, emergency services, and partial hospitalization (Soumerai et al. 1994).

Fail-first strategies in which a person must first try a particular drug from a family, such as SSRIs before access to other options are approved, have been adopted by some states either directly or through managed care plans. The pharmaceutical industry, advocacy and physician groups have often opposed these techniques. A more recent tactic meeting with more acceptance and some success has been to focus on physician practices such as prescribing multiple drugs from one family which can increase costs and for which there is little scientific evidence to support the practice. Usually, other quality measures such as recommended dose ranges and multiple prescribers of a drug or drug class are also targeted. Missouri, for instance, implemented the approach in 2003 (Bergman et al. 2006). Anticipated savings for Missouri in 2004 was $7.7 million (Bergman et al. 2006).

Those individuals enrolled in traditional Medicare plans were without any prescription drug benefit to cover these costly medications until the Medicare Prescription Drug, Improvement, and Modernization Act (MMA) of 2003 went into effect in 2006. This act allows Medicare beneficiaries to enroll if they choose in one of many prescription drug plans. Individuals who were dually eligible for Medicaid and Medicare under this plan, in most circumstances and for most drugs now have their prescriptions paid for under one of the Medicare plans. These plans administered by the private insurance industry utilize managed pharmacy benefit techniques albeit under some government regulations. Solutions to the rising drug cost problem are not easy. Canada controls medication costs via federal regulation. However, while prices are lower than in the US, Canadian prescribing trends toward newer, more expensive psychotropics led to a 216% increase in cost for these drugs between 1992 and 1998 (Dewa and Goering 2001).

Differences in managed mental health care programs abound. Debate continues regarding which programs are successes and the reasons for programs failing. Croze (2000) presents programs in Colorado, Iowa, and Massachusetts as having achieved improvements in some of the following areas: decreased costs, increased penetration, decreased hospital admissions, increased array of services, and decreased waiting times. How much more efficiency and cost saving may be gained by further use of managed care is not clear. Historically, those areas which relied more heavily on inpatient care have produced earlier and more dramatic results using managed care through decreasing the use of inpatient care by decreasing admissions and decreasing length of stay. There may now be more areas,
similar to the Oregon counties, studied by McFarland et al. (2002) in 1995 in which one county switched to a managed Medicaid system while the other remained fee-for-service. Both counties showed decreased length of stay from 1994 to 1996. The county which changed to managed care retained its slightly longer length of stay. As length of stays shorten, in this case to 6 days, it becomes more difficult to discern differences between groups. In some areas there may be little left to squeeze from the inpatient care system.

Finally, greater appreciation by both the managed care industry and by state and local governments about the complexities of providing care for the SMI population may also temper the initial enthusiasm for public managed mental health care. Concerns about the ability of managed care systems, which have traditionally served populations with large numbers of relatively healthy, well functioning individuals, to serve a disabled, severely and persistently ill population remain. Boothroyd et al. (2002) recommend caution in considering risk arrangements for such vulnerable populations on the basis of their finding that Florida Medicaid enrollees in plans in which providers bore financial risk reported less use of both general medical and mental health services and more problems with access than those enrolled in fee-for-service plans. Satisfaction with general medical services but not with mental health services was also adversely affected by the provider bearing risk (Boothroyd et al. 2002).

The structure of risk sharing arrangements varied greatly across the five SAMHSA demonstration sites which targeted adults with severe mental illness; but all five sites showed an inverse relationship between assumption of risk and the application of strict utilization review (Ridgely et al. 2002). Other differences between sites included how substance abuse and pharmacy benefits were provided (Ridgely et al. 2002). Monitoring the effect of managed mental health care on people with severe mental illness will remain a challenge for the upcoming years.

Emerging Directions in Care Management

It is clear that the more sophisticated managed care approaches have succeeded in controlling mental health care costs while addressing concerns about quality that were serious and legitimate regarding early cost management programs. A 1993 report by the actuarial consulting firm Milliman and Robertson cited experiences with five major US firms that implemented mental health managed care approaches, achieving consistent savings and increasing benefits or use of services among the covered population (Melek 1993). As a result, the growth in use of mental health managed care has been extraordinary. By 1993, specialized behavioral managed care firms were responsible for mental health care for more than 80 million Americans.

Managed care programs in mental health have been more successful at balancing cost control, access to care, and quality than approaches that emphasize benefit limits and payment approaches, such as DRGs. Done well, managed care efforts blend economic incentives with clinical decision-making in the context of a prepaid system of care. Yet, these arrangements cover the gamut from the relatively crude cost management programs that emphasize rationing to sophisticated third-generation efforts that emphasize quality. The trend among larger employers is clearly toward the more sophisticated managed care approaches. However, future directions are uncertain, given the extraordinary cost pressures that still exist in health care.

Kunnes (1994) predicted that future approaches to mental health services will move beyond managed care as it is now known. He forecasted the increased development of “integrated delivery systems” that are “vertically and horizontally integrated, managed, very patient friendly, regional, and inclusive of both behavioral health care and medical/surgical services” (Kunnes 1994). Under this scenario, provider networks will increasingly take on their own insurance functions, capitalizing on their local reputations and relationships while recognizing the need to manage risk. Kunnes also predicted that “distinctions between public and private delivery systems will break down” (Kunnes 1994). Whereas this is only one of many possible future scenarios, it illustrates a direction that builds on emerging developments in the mental health field: increased access, cost control, and strategies to achieve these goals that use economic incentives, clinical decision-making, and organizational approaches.

The Quality Improvement Movement

Mental health treatment has also been affected by the quality improvement methods and approaches that have evolved from the work of W. Edwards Deming and other industrial quality improvement “gurus.” Central themes include the idea of quality improvement as a continuous process, the importance of measurement in aiding in and defining changes in quality, and an orientation to customer requirements and satisfaction. These ideas have been reflected in the accreditation standards of the Joint Commission on Accreditation of Health Care Organizations and signal the evolving direction of quality improvement. Bologna and Feldman predicted that the direction of quality efforts in mental health will evolve toward continuous improvement: “A feedback loop in which clinical outcomes shape patient treatment matching, which in turn changes outcomes, is the core mechanism from which many of the most dramatic changes in behavioral health care will evolve” (Bologna and Feldman 1994, p. 32).

Knowledge of the terms and processes used in quality improvement is essential for mental health professionals. Beaudin and Beaty (2004) describe strategies currently used in behavioral health quality improvement. Quality assurance emphasizes compliance with regulation standards and targets individual performance rather than examining processes. Quality improvement surpasses these minimum standards in order to improve outcomes by enhancing effectiveness and efficiency. Quality improvement targets changes at systems and processes. A basic strategy from Deming’s work is Plan-Do-Check-Act (PDCA). Planning involves process investigation, date collection and analysis. In the Do phase, the plan is implemented. The effects of implementation are measured to see if it is having the desired effect in the Check phase. The Action phase leads to the new method being adopted or abandoned, evaluation of corrective plans and communication of results. Examples of application of quality improvement models reviewed are increasing the rate of outpatient follow-up after psychiatric hospitalization, better detection of delirium and other organic disorders in the elderly and better access to specialty behavioral health care.
Defining and Improving the Quality of Mental Health Care

The issue of the quality of mental health treatment presents several paradoxes. One is the gap between solid knowledge of the general efficacy of treatment and the absence of much specific research that links particular interventions with particular conditions at defined times. A second paradox involves the gap between findings of treatment efficacy (the demonstrated impact of care under research conditions) and broader treatment effectiveness (the results achieved under typical treatment conditions).

The general efficacy of mental health care is well established. In a comprehensive review of research on the epidemiology of mental illness and the effectiveness of care, the National Advisory Mental Health Council concluded that “for persons with serious mental disorders, the chances of obtaining significant benefit through treatment have never been better…a growing body of research knowledge from clinical trials has verified the efficacy of these treatments… this compares very favorably with other areas of medicine” (National Advisory Mental Health Council 1993, p. 1450).

There is also considerable evidence of the efficacy of particular categories of treatment. The volume of research on the efficacy of psychotherapy, for example, is extraordinary. In an analysis of the psychotherapy literature, Lipsey and Wilson (1993) concluded that the evidence of the benefits of psychotherapy is well established. At the same time, the diversity of mental illness and its treatments imposes a humbling reality. Research has not yet established clear findings linking the nature, method, and timing of interventions to particular conditions. Atkinson et al. (1992) concluded that not enough was known about which treatments work, the particular circumstances under which people with serious mental illness benefit, or how services should be sequenced or combined most effectively. Similar issues exist even within the psychotherapy research literature. Lipsey and Wilson (1993) found a relationship between the strength of the therapist–patient alliance and the effectiveness of treatment and the satisfaction with treatment predicted better outcomes, but their analysis did not correlate specific methods with conditions or diagnoses. Thus, there is considerable evidence about the effectiveness of mental health treatment and about which general types of treatment are helpful with which disorders. However, clear data establishing specific parameters for care of particular conditions under defined circumstances remain elusive.

At the same time, fiscal pressures and expectations of patients and payers are leading to an increasing emphasis on defining and improving the quality of treatment. With these pressures, approaches to address quality are evolving from crude, broad approaches like licensure and certification of professionals or programs to increasingly specific and focused strategies such as treatment guidelines for specific conditions.

The Evolution of Quality of Care Strategies

The most basic approaches to ensuring the quality of care are licensure of practitioners as adequately qualified, certification of providers or agencies for the purpose of reimbursement, and accreditation of provider organizations by independent bodies.

Licensure

Licensure of practitioners by states is the most basic and universal approach to quality. Licensure is based on training, a review of qualifications, and sometimes passage of an examination. Frequently, professionals must satisfy requirements for continued education to maintain their licensed status. As an approach to ensuring quality, licensure is basic; it focuses on the preparation of the practitioner but does not address the actual conduct, processes, or outcomes of care. Professional licensure is required to be able to practice or, generally, to accept reimbursement. Thus, licensure provides a kind of basic consumer protection, ensuring that patients are not treated by untrained or ill-prepared individuals.

Certification

In most states, certification of provider organizations by state authorities is the equivalent of professional licensure; in fact, the terms licensure and certification of agencies are sometimes used interchangeably. Certification standards are typically designed to ensure that provider organizations are minimally qualified and usually address such issues as the presence of adequate and safe facilities, acceptable policies and procedures, qualified and licensed staff, appropriate record-keeping and treatment-planning procedures, and the like. Like professional licensure, certification is required as a threshold to provide care, typically being a requirement for public reimbursement or contracts. Certification can ensure that appropriate preconditions for quality care are present but cannot ensure that quality care is actually provided.

Accreditation

Various independent organizations have developed voluntary standards and review mechanisms that they employ to accredit provider organizations. The most significant accrediting body in health care is the Joint Commission on Accreditation of Health Care Organizations, which predominantly accredits hospitals but also addresses health systems, clinics, and mental health centers. Other accrediting organizations that touch on mental health include the Commission on Accreditation of Rehabilitation Facilities, the Council on Accreditation (which specializes in counseling and family service organizations), and the Utilization Review Accreditation Council. The last organization is the newest and reflects the demand from both payers and treatment professionals that standards be developed to address the growing utilization review and managed care industry.

Accreditation has similarities to state certification and involves review of facilities, staffing, policies and procedures, and so on. However, accreditation is a voluntary process (although increasingly, purchasers insist on accreditation as another assurance of quality). Accreditation is often more demanding than state certification standards, for example, it may address evidence of the actual use of practices such as quality assurance or review of staff members’ credentials. However, accreditation, like licensure and certification, indicates only that the conditions for quality care are present—or at least they were present at the time of the most recent survey. Given the increased concern about cost and cost effectiveness that characterizes the current health care environment, more specific methods are increasingly being developed.
Developing Approaches to the Quality of Care

Beyond licensure, certification, and accreditation a variety of approaches are used to respond to demands for quality of care data. A direct approach that is increasingly in vogue is assessing patients’ satisfaction with care received. Whereas “customer satisfaction” is a legitimate issue to assess on its own merits, there is some research justification for assessing patients’ satisfaction as an approach to quality. In Lipsey and Wilson (1993) meta-analysis of psychotherapy research, patients’ satisfaction was related to outcomes, a finding that also emerged from the study by Roth et al. (1995) of outcomes for SMD patients in community care.

Owing to the increasing understanding of satisfaction as an outcome-related variable and because of its inherent value, managed care firms are increasingly requiring the use of satisfaction measures by practitioners. According to Freeman and Trabin, “The demand for data on quality has led to almost universal implementation of customer (patient) satisfaction measurement through the use of questionnaires as a first step. Measuring self-reported patient satisfaction is often easier than measuring clinical outcomes. Similarly, provider network satisfaction ratings and patient satisfaction measurement queries are finding their way into the audits of managed care plans performed by employee benefits managers” (Freeman and Trabin 1994, p. 30).

Another quality-related practice that is growing in acceptance is the use of standardized assessment scales as an aid to assessment of patients and treatment planning and to assist in checking progress in treatment. Although there is not yet evidence to support the use of standardized measures to dictate treatment regimens, there can be little doubt that these measures provide an element of objectivity and can serve as a reference point. The use of these measures is also generally considered important as documentation that treatment has progressed according to accepted professional standards. The Institute of Medicine’s report “Improving the Quality of Health Care for Mental and Substance Use Conditions” emphasized the importance of clinicians and organizations using standardized questionnaires or other assessment tools to measure outcomes of treatment to contribute further to the evidence base of treatments and to monitor and enhance the quality of care (Pincus et al. 2007). Clinicians who read outcome reports based on standard measures of patients at baseline and throughout treatment had patients who reported greater improvement (Azocar et al. 2007).

Practice Guidelines

Research on the effectiveness of different patterns of care is also enabling the development of practice guidelines—recommended approaches to the treatment and management of particular conditions. These guidelines are intended to strike a balance between specificity when it is possible and deference to the psychiatrist’s judgment when it is appropriate. Practice guidelines are typically developed by consensus panels of researchers and psychiatrists on the basis of the state of knowledge that exists with respect to a particular condition. Guidelines for the treatment of psychiatric disorders have been published by the American Psychiatric Association (see Table 86–14) (American Psychiatric Association 2006). Other groups are also working on treatment guidelines in mental health. The Agency for Health Care Policy and Research and the NIMH funded a Patient Outcome Research Team (PORT) study to review the literature, study actual practice patterns, and make recommendations for the treatment of schizophrenia. The approach has been used previously to develop treatment recommendations for cataract surgery, hip replacement, and other conditions, but the PORT study of schizophrenia was the first in mental health. The PORT study recommended 30 interventions for the treatment of schizophrenia. The majority of the recommendations focused on adequate use of antipsychotics and other medications but included the use of electroconvulsive therapy, selected forms of psychotherapy (nonpsychodynamic), family support and psychoeducation, vocational rehabilitation, and assertive community treatment (Lehman and Steinwachs 1998). A challenge to implementation of recommended practices is the picture that is emerging of actual practice trends that favor medications over psychotherapy and other psychosocial interventions. West’s group assessing conformance to the PORT and APA guidelines for the treatment of schizophrenia noted that conformance for psychopharmacologic treatment was high (99% received antipsychotic medication with 83% receiving treatment with atypical antipsychotics at target ranges), conformance for a variety of recommended psychosocial treatments was low ranging from 0% for vocational rehabilitation to 43% for illness education or psychotherapy (West et al. 2005).

Similarly, the outpatient treatment of depression has been noted to increasingly favor treatment with antidepressant medication over psychotherapy even for those types of depression for which psychotherapy is as effective (Olfson et al. 2002). This study revealed that while overall rates for treatment of depression increased between 1987 and 1997 from 0.73 per 100 persons to 2.33 per 100 persons the increase was almost entirely due to an increase in antidepressant use. In 1987, 37.3% of people were treated with antidepressants compared to 74.5% in 1997. At the same time the proportion of people receiving psychotherapy for depression declined from 71.1% to 60.2%. A comparison study of the trends in overall use of outpatient psychotherapy showed no significant change with rates between 1987

### Table 86–14 APA Practice Guidelines for Treatment of the Following Psychiatric Disorders Have Been Developed

- Acute stress disorder and post traumatic stress disorder
- Alzheimer’s disease and other dementias
- Bipolar disorder
- Borderline personality disorder
- Delerium
- Eating disorders
- HIV
- Major depression
- Nicotine dependence
- Obsessive compulsive disorder
- Panic disorder
- Psychiatric evaluation of adults
- Schizophrenia
- Substance use (Alcohol, cocaine, opioids)
- Suicidal behaviors
Many efforts to standardize patterns of care whether they be more comprehensive approaches such as the APA guidelines or PORT recommendations or more restrictive medication guidelines or algorithms have heavily favored newer pharmacologic agents. A recent challenge to these guidelines has been the release of two large, longitudinal studies (CATIE and CUtLASS) which has raised some questions about the previously presumed clinical superiority and safety of newer drugs which were given preferred status in some guidelines (Lieberman et al. 2005, Jones et al. 2006). Beyond the challenge to some of the recommended practices, these studies have raised cost effectiveness questions which is further addressed in an earlier section of this chapter “Effective treatments and defective funding.” The clinician using practice guidelines should consider the sponsorship and support of the project (including the funding source), by whom the guidelines were developed, the process used and the goals of the guidelines. Some guidelines focus solely on medication algorithms while others review all treatment modalities. Some guidelines or reviews adhere more strictly to using randomized controlled trials (RCT) while other venture recommendations beyond these especially when RCT data is limited. Some guidelines are more user friendly then others. Still, with these caveats in mind, the future will find increased use of practice guidelines in mental health and in health care in general.

**Prospects for the Future**

Absent revolutionary changes in the basic landscape of health care—which are certainly possible—the trends described in this chapter are likely to continue. At the same time, the rate and path of change are unpredictable; the complexities of the health care system and of mental health care in particular make this virtually certain. An appreciation of the dynamics and general directions of change is most relevant in this uncertain context.

As the discussion earlier in the chapter illustrates, reform in mental health has been tied to social and political trends in the larger society, and emerging clinical innovations and treatment approaches have often been linked with parallel social changes. This is an important dynamic that is likely to persist. The increasing diversity of society may thus be linked to the reduction in the stigma of mental illness and to seeking help that has been so dramatic in the past generation. On the other hand, there remain strong signals of intolerance, and the income and class differences between rich and poor are not being reduced. The fate of the most seriously and persistently mentally ill, especially the homeless mentally ill, may rest as much on these trends as on advances in treatment.

The relationship between the public and private mental health sectors has been one of the most important and underestimated factors shaping mental health policy. Psychiatry emerged as a profession within the US medicine, by and large, in the public sector of the 19th century. In more recent years, the story has been dominated more by separate and discrete private and public sector systems, for those with means and less serious conditions on the one hand and the seriously mentally ill on the other.

There are numerous signs at this time of the blurring of lines between public and private sectors. The government insurance programs (Medicare and Medicaid) involve publicly financed but increasingly privately provided care. The financial pressures in the private health care sector are increasingly reminiscent of public sector limits. Although the Health Security Act failed to achieve passage in 1994, its proposition that universal, nondiscriminatory mental health coverage should be achieved—requiring the integration of public and private resources—struck a chord among health and mental health practitioners and policymakers.

The gradual fusion of many public and private resources in mental health is also augured by developing trends in the organization and financing of care. It is now abundantly clear that the complexities of treating mental illness cannot be addressed by the same economic approaches that have been used for inpatient and outpatient physical health care. At the same time, the financing and organization of most health care are changing, with much broader reliance on HMOs and the continued development of new provider collaboratives and networks. The implication is that the days of loosely regulated fee-for-service practice are essentially over. Whether the label is managed care, HMO, or practice network, the trends are toward strong controls and expectations by purchasers, collaborative practice, targeted use of expensive interventions, and increased focus on the customer—patient’s satisfaction.

Trends in the definition and measurement of quality will buttress these developments. Whereas mental health care will continue to be artful and dependent on professional judgment, research advances and payer–customer demands will lead to the increased use of standardized assessments as an aid to clinical decision-making. Practice guidelines will suggest the optimal approach to and sequencing of care. Increasingly, the care of individual patients will be shaped by data-based feedback on their progress and needs.

Elements of this future may resemble an Orwellian new world in the eyes of some, but there is a positive side as well. The basic characteristic of a profession is the ability to define itself, and psychiatry remains positioned to define its role as mental health care evolves into the 21st century. Similarly, changes in payment systems and approaches to diagnosis and treatment will be used by the best practitioners to their advantage—and most particularly to their patients’ advantage. The evolution of more effective and focused treatments, coupled with the reduced stigma of mental illness, may make the new era of psychiatry and mental health care the most productive and exciting era yet.

Psychotherapeutic and Psychosocial Treatments
Psychoanalytic theory provides the modern clinician with a comprehensive system for the understanding of personality development, the meaningfulness of human conflict and emotional pain, and the mutative factors within the doctor–patient relationship. Psychoanalysis is a general psychology, a developmental theory, and a specific treatment. Since its inception, psychoanalytic theory has undergone numerous and substantial revisions. Its history and the movements that contributed to its evolution are described in Chapter 28. With respect to psychoanalysis as a treatment approach, its history has been punctuated by persistent attempts both to simplify the psychoanalytic technique and to shorten its duration of treatment. The synonymous terms psychoanalytic psychotherapy, psychoanalytically oriented psychotherapy, psychodynamic psychotherapy, and expressive psychotherapy have come to represent the most coherent of these attempts.

For many years after World War II, there was an intense controversy among psychoanalysts about the merit of psychoanalytic psychotherapy because it was considered to be a diluted form of psychoanalysis with poorly defined techniques and goals. Today, for a number of reasons, this issue seems to be less important. First, and most recently, managed care, with its emphasis on cost containment and fiscal accountability, has attributed greater importance to episodic care through briefer psychotherapeutic interventions. Second, compared with 20 years ago, psychoanalysis as a treatment option is no longer equitably reimbursed by third-party payers. As a result, many analysts devote more of their professional time to psychoanalytic psychotherapy than psychoanalysis. Third, with only a few notable exceptions, psychoanalysis has all but moved out of psychiatry departments in academic health centers, and most residency training curricula now focus much more on the basic and practical applications of psychoanalytic theory and technique and not on more traditional psychoanalytic metapsychology. Moreover, during the last 35 years, many new, brief, psychoanalytically informed psychotherapies have been developed. These include, but are not limited to, the methods of Malan (1976), Mann (1973), Sifneos (1979), Davanloo (1978), Horowitz et al. (1984), Luborsky (1984), Milrod et al. (1997), and Strupp and Binder (1984). Manual-driven psychotherapies with demonstrated treatment efficacy, such as interpersonal psychotherapy and some forms of cognitive–behavioral psychotherapy, also incorporate many traditional psychoanalytic notions about the physician–patient relationship and the role of interpretation. Last, psychoanalytic theory has remained relatively dynamic and has integrated and consolidated the advances from object relations theory, self psychology, interpersonal theory, and the renewed interest in the study of psychic trauma. This has permitted, in the case of severe personality disorders and serious developmental trauma, the psychodynamic treatment of a broader range of psychological problems than was previously considered possible through classical psychoanalysis.

What Is Psychotherapy?

It is customary to define psychotherapy in a broad fashion as comprising three distinct components: a healing agent, a sufferer, and a healing or therapeutic relationship (Frank and Frank 1991). Strupp (1986) specified that psychotherapy is the systematic use of a human relationship for therapeutic purposes of alleviating emotional distress by effecting enduring changes in a patient’s thinking, feelings, and behavior. The mutual engagement of the patient and the psychotherapist, both cognitively and emotionally, is the foundation for effective psychotherapeutic work.

Whereas there are many different types of psychotherapy (Figure 87–1), the core task of the psychoanalytic psychotherapist is to make contact with and comprehend, as thoroughly as possible, the patient’s subjective inner world to engage in an analytical (i.e., interpretive)
conversation about it (Ornstein and Kay 1990). This core task implies that all psychoanalytic psychotherapies may be further defined in terms of three operations: accepting, understanding, and explaining (Ornstein and Ornstein 1985) (Table 87–1). First, and more specifically, the therapist must engage with the patient by accepting the subjective experience of the patient’s emotional pain and conflict. This is achieved through the establishment of a therapeutic dialogue based on an empathic, nonjudgmental rapport. Second, within the process of listening to, and feeling with the patient, the therapist will begin to develop an understanding of the intricacies of the patient’s plight. Much of what the therapist observes may at first remain outside of the patient’s conscious awareness, manifested in the form of reenactments and reliving of earlier experiences within the therapy, rather than in deliberate, conscious, descriptive communication. Last, by the sharing of this beginning understanding with the patient through a simultaneously empathic and interpretive mode, both arrive at a deeper appreciation for the genesis of, and the reasons for, the patient’s symptoms. The shared relationship in which understanding is gained is no less instrumental in achieving change than are the insights and modified perceptions that may result from the psychotherapeutic experience.

**Expressive–Supportive Continuum**

Traditionally, to the degree that psychoanalytic psychotherapy has focused on the recovery of repressed psychological material, it has been called “expressive” and has been distinguished from the supportive psychotherapies, which have concentrated on the shoring up of certain defense mechanisms. Supportive psychotherapy has been the traditional treatment approach for more disturbed patients, for example, those with debilitating thought and personality disorders. Supportive treatment has also been helpful to patients who are not necessarily suffering from serious underlying impairments but whose symptoms are reactive to immediate identifiable precipitants, such as loss, illness, or other major life change. Expressive psychotherapy, on the other hand, has been concerned with the uncovering of unconscious wishes, beliefs, needs, and memories through the analysis of defense mechanisms and has been indicated for the treatment of neuroses and related conditions, as well as traumatic disorders and less dysfunctional personality disorders.

Such a clear-cut distinction is now viewed as arbitrary and scientifically unsound. Indeed, all effective psychoanalytic psychotherapies, including psychoanalysis, use supportive measures. Moreover, effective supportive psychotherapy is frequently psychoanalytically informed, and no systematic studies have demonstrated that the behavioral change and symptom relief from supportive treatment are inferior to, or less enduring than, those gained from expressive therapies (Wallerstein 1986).

It is more appropriate, therefore, to conceptualize psychoanalytic psychotherapy as being on a continuum of expressive to supportive (Luborsky 1984, Gabbard 1994). This implies that any given treatment might employ more or less expressive and supportive interventions, depending on what is transpiring within the psychotherapeutic process. An important skill of the psychoanalytic psychotherapist is then the ability to employ the appropriate balance of both expressive and supportive interventions as dictated by the needs of the patient. Finally, the conceptualization of an expressive–supportive continuum also facilitates the establishment of therapeutic goals, interventional plans, and indications for individual psychoanalytic psychotherapy (Gabbard 1994) (Table 87–2).

Clinical Vignette 1 illustrates the combination of expressive and supportive measures.

Clinical Vignette 1
Ms. S entered twice weekly psychotherapy because of the discouraging lack of career advancement. It became abundantly clear to the therapist that each time the patient was acknowledged by her peers for her outstanding contributions to her law firm, she became profoundly depressed and the quality of her work deteriorated. The therapist shared this observation with Ms. S, who became anxious and frightened. The patient worried that perhaps her reaction to the therapist’s words indicated she was “sicker” than she thought. The therapist reassured the patient that she was not “going crazy,” and stated that it was important to understand the meaningfulness of the response to the intervention as had been the case with all issues in the psychotherapy.

Theory of Psychoanalytic Psychotherapy

Basic Concepts
Because psychoanalytic psychotherapy is derived from psychoanalysis, it is necessary to appreciate the fundamental contributions. Five different but complementary views of mental phenomena constitute the metapsychology or theoretical edifice of psychoanalysis. Whereas none of the five constructs is comprehensive or sufficient to explain all of human behavior, each one has contributed a significant component to the current theory and technique underlying psychoanalytic psychotherapy. Freudian or classical psychoanalysis is, above all, a psychology based on mental conflict in which human beings are constantly defending against strong, unconscious, biologically based, intro psychic needs and desires. The five metapsychological viewpoints attempt to explain this psychology (Table 87–3).

Table 87–3 Five Metapsychological Viewpoints of Psychoanalytic and Associated Constructs

| Topographical | Conscious, preconscious, unconscious |
| Dynamic | Conflict and resistance |
| Structural | Ego, id, and superego |
| Economic | Psychological investment in ideas and affects |
| Genetic | Past lives in the present, repetition–compulsion |

The topographical point of view states that there are varying levels of mental awareness. Feelings and thoughts may be unconscious, preconscious, or conscious. Repression, about which there is recent neuroscientific support (Anderson and Green 2001, Anderson and Levy 2006, Boag 2006), is the most basic of defense mechanisms that keep conflicted feelings and thoughts inaccessible, thereby preventing emotional discomfort. In addition, there are imaging investigations that demonstrate a specific mechanism in the medial prefrontal cortex for inhibiting memory retrieval and storage.

The dynamic point of view postulates that mental processes are both fluid and the result of opposing forces. This point of view supports the concepts of both conflict and defense. Defense refers to that universal unconscious process whereby patients struggle against the conscious awareness of anxiety-provoking mental content, such as memories, needs, wishes, or fears. There is neurobiological evidence for the existence of signal anxiety, which functions as an alerting or warning system to prompt defense mechanisms (Wong 1999). Resistance refers to defenses as they appear in the therapy when the patient unconsciously protects himself or herself against the anticipated pain of such awareness and therefore, to some degree, against progress in treatment.

The structural point of view is based on a tripartite model of the mind consisting of ego, superego, and id. Each of these theoretical concepts is associated with certain functions. The id, characterized by primary process thinking (does not follow rules of logic, lacks sense of space and time, thoughts and actions are equivalent) is considered the repository of irrational and illogical infantile wishes and impulses; the superego, narrowly defined, represents moral and ethical prohibitions; and the ego is that executive portion of the mind that mediates between the id and superego by allowing a person to establish a stable balance between early powerful feelings and impulses and the demands of socialization. The ego mediates, therefore, between the demands of the unconscious and those of external reality. The ego is conceptualized as containing not only the defense mechanisms but the experiencing and observing functions of the mind as well. Secondary process thinking, characteristic of the ego, provides the capacity for reality testing, logical thought, and appreciation of causality. Ego strength, a significant indicator for patients entering psychoanalysis and psychoanalytic psychotherapy, refers to the overall capacity for both personal and social competency.

The economic point of view attempts to explain the nature of psychic energy as it relates to the expression of feelings and ideas and is helpful in understanding defense mechanisms, those unconscious processes that ward off anxiety and other painful affects. As will be explicated, appreciating the role of defense mechanisms is critical to both understanding why patients behave in specific ways and appreciating the concept of transference.

The genetic point of view, the fifth perspective, addresses the centrality of those childhood experiences, especially traumas, that may account for strong feelings, conflicts, and symptoms later in life. This view is best expressed by the statement that the past lives in the present, meaning that past relationships or the representation of past relationships exist in the mind as if they were present relationships in the here and now. It also provides an explanation as to why certain dysfunctional or self-defeating behaviors are repeated throughout life in an attempt to master earlier psychological problems. It is responsible for the unique transference perceptions and reenactments each patient experiences in relation to persons in her or his present life, including the therapist within the process of psychoanalytic psychotherapy.

The theoretical concepts that derived from these five points of viewing mental activity constitute, more or less, the assumptions behind all psychoanalytic psychotherapy. These include, most importantly, the role of the unconscious, the centrality of transference, the characterological defense mechanisms, and the resistance to self-awareness and thereby to progress in the therapeutic setting. Of secondary importance, but nevertheless closely related to the unconscious, is the concept of psychic determinism, namely,
that people behave in specific ways for specific reasons that are mostly outside of awareness. No experience or memory, according to psychoanalysis, is ever lost but resides in the unconscious, which continues to influence current and future ways of experiencing feelings, thoughts, and behaviors. Advances in cognitive neuroscience have supported the notion that many significant experiences throughout life remain outside of awareness.

**Transference and Resistance, Countertransference, and Counterresistance**

Transference and resistance constitute the two most distinctive features of psychoanalytic psychotherapies. Transference is defined as those perceptions of, and responses to, a person in the here and now that more appropriately reflect past feelings about, or responses to, important people earlier in one’s life, especially parents and siblings. Whereas transference experiences are ubiquitous in everyday life as well as in psychotherapy, the development of a transference neurosis, or the recreation of a sustained, intensely affective, conflictual relationship to the person of the psychoanalyst, is more likely to occur within the analytical setting. It is promoted by characteristics of that therapeutic interaction (e.g., use of couch, frequent sessions, therapeutic regression, abstinence position of the analyst) and is more likely to be the focus of interpretation in psychoanalysis. However, supportive measures traditionally characteristic of other forms of treatment also have an important role in psychoanalysis. Psychoanalytic psychotherapy stresses the importance of transference within the treatment relationship, but it differs from psychoanalysis in that it does not, to the same degree, promote the depth and intensity of the transference.

Transference is demonstrated by the two patients in a brief clinical vignette (see Clinical Vignette 2).

**Clinical Vignette 2**

A patient comments at the end of the first session that the therapist reminds her of her beloved sister who is bright and generous, and whose style of home decorating is beautiful and warm. The patient was apprehensive about beginning psychotherapy but feels more hopeful and comfortable now that she has met the therapist and seen her office.

Another patient finds the office of this same therapist “sterile, not warm or homey and intentionally unrevealing” of who the therapist is as a person. The patient interprets this “professional decor” as an indication that she should not hope for warmth or emotional involvement from the therapist.

Countertransference is variously defined as (1) the analyst’s or psychotherapist’s transference reactions to the patient, (2) his or her reactions to the patient’s transferences, and (3) any reactions, feelings, and attitudes of the analyst or therapist toward the patient, regardless of their source. Such responses to the patient were once viewed as deviations from the ideal of a consistently bland and comfortable experiencing of the patient by the analyst or therapist. Countertransference reactions were also conceptualized as impediments to progress within the treatment, that is, as interferences in the therapist’s ability to understand the patient. They are currently more broadly understood as manifestations of the requisite engagement by the therapist or analyst in the emotional process of treatment. Moreover, these reactions are a rich source of understanding of the patient’s experience as it touches the therapist affectively. Although countertransference feelings are at times uncomfortable for the therapist and a challenge to monitor and process, they are understood as a reflection of the glue of the relationship without which no real connection or significant change can occur.

Clinical Vignettes 3A–3C illustrate countertransference reactions in response to intense feelings of helplessness, irritation, and sexual feelings.

**Clinical Vignette 3A**

Dr. J was treating a 30-year-old depressed cardiac transplant patient in brief psychotherapy. The onset of the patient’s depression coincided with clinical evidence that his new heart was being rejected. The patient’s course deteriorated rapidly, and he was hospitalized. Dr. J continued to see the patient as he awaited the highly unlikely possibility of a new donor. After each of the sessions, Dr. J noted that he was exceptionally tired. On the way to his session with the patient that occurred on Christmas Eve, Dr. J stopped at the nursing station and prepared a plate of Christmas cookies for the patient, something he had never done for a patient regardless of the treatment setting.

**Clinical Vignette 3B**

Dr. C was treating a beginning college student who was having significant difficulty adjusting to her new environment complicated by the breakup of a long-standing relationship prior to the start of school. In the first weeks of treatment, the young woman had two overdoses and the patient’s mother called the therapist frequently. Dr. C forgot that she was scheduled to meet with her patient, which precipitated further demanding behavior and a request for hospitalization. With her supervisor’s assistance, Dr. C was better able to appreciate her irritation and resentment of both the patient and her mother.

**Clinical Vignette 3C**

A resident was treating an attractive young woman. He soon noticed that he was permitting the sessions to extend beyond his customary 50 minutes. He also became aware of a sense of excitement about his sessions with this patient even to the point of being aware that he paid particular attention to how he dressed on the days of his meetings with this young woman.

Resistance is broadly defined as the conscious or, more often, unconscious force within the patient opposing the emergence of unconscious material. Resistance must be understood not as something the patient does to the therapist, but rather as the patient’s attempt to protect herself or himself by avoiding the anticipated emotional discomfort that accompanies the emergence of conflictual, dangerous, or painful experiences, feelings, thoughts, memories, needs, and desires. Resistance occurs through the use of unconscious
mental operations called defense mechanisms, for which there is substantial research support (Vaillant 1992, Horowitz et al. 1995) (Table 87–4). The recognition, clarification, and interpretation of resistance constitute important activities of the psychoanalyst and the psychoanalytic psychotherapist, both of whom must first appreciate how a patient is warding off anxiety before understanding why he or she is so compelled. (The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision [DSM-IV-TR] notes the potential helpfulness of a Defensive Function Scale, which requires further study but may elucidate both defense levels and specific defense mechanisms in terms of adaptation, mental inhibitions, image distortion, disavowal, action levels, and defensive dysregulation levels; American Psychiatric Association 1994, pp 752–753.)

*All defense mechanisms are involuntary and unconscious and are arranged approximately from immature to more mature defenses.

An example of resistance is illustrated in the encounter given in Clinical Vignette 4.

Clinical Vignette 4

Ms. C entered psychotherapy because of anxiety and depression. Later in the treatment, evidence emerged that many of the patient's symptoms were related to her significant sexual conflicts and inhibitions. The therapist noted that each time the subject of her sexual activities was approached, Ms. C became confused and anxious and was unable to remember what had been discussed from one session to the next. This pattern of response was involuntary and left the patient frustrated and pessimistic about the ultimate success of therapy.

Counterresistance refers to those psychological processes within the therapist that impede therapeutic progress. These are reactions to some aspect of the treatment experience that unconsciously create anxiety in the therapist. Such occurrences become accessible first to conscious awareness and then to self-study or self-analytical work, often in the form of a mistake or a symptom experienced in a therapy session. As an example, the therapist might forget the patient's appointment time or feel sleepy or bored during a therapy session. Countertransference feelings may also be manifested in dreams or fantasies about the patient. Analysis of such symptoms of countertransference not only can facilitate progress in a stalled treatment but may lead to significant growth in self-understanding by the therapist, as well as improved understanding of the patient.

Basic Technique

As noted, the analysis of transference by the repeated interpretation of resistance is the primary activity of the psychoanalyst and an important one for the psychoanalytic psychotherapist. To promote the patient's examination of the phenomena of transference and resistance, both the analyst and the therapist are guided by principles that establish a confidential, safe, and predictable environment geared toward maximizing the patient's introspection and focus on the therapeutic relationship. The patient is encouraged to free-associate, that is, to notice and report as well as she or he can whatever comes into conscious awareness. In the case of psychoanalysis, the depth of the therapeutic process is enhanced by the patient's lying down with the analyst out of the patient's visual range, with a modest level of verbal activity by the analyst, and by meeting frequently, usually four or five times weekly for 45–50 minutes for a number of years (American Psychiatric Association 1985) (Tables 87–5 and 87–6).

The characteristics of psychoanalytic psychotherapy are manifested. Although the patient has a strong tendency to experience the analyst as a more consolidated transference neurosis, there will be some affective disorders with and without medication (e.g., major depression, dysthymia). The analyst and psychoanalytic psychotherapist of recognizing and accepting the patient's wishes and emotional needs, particularly as they emanate from transference distortions, while abstaining from direct gratification of those needs through action. Abstinence is a principle that guards against the therapist's gratification at the patient's expense. For example, in psychoanalysis, as the treatment experience deepens into a more consolidated transference neurosis, there will be a strong tendency by the patient to experience the analyst as the important person in the patient's life around whom the characteristic conflictual issues are manifested. Although it is technically proper to speak of the development of a transference neurosis only in psychoanalysis, many patients in psychoanalytic psychotherapy also develop strong transferences within their treatment experiences. By maintaining a neutral and abstinent position with respect to the patient's needs and wishes, the analyst and psychotherapist create a safe atmosphere for the experiencing and expression of highly charged affects required for the patient's motivation for continued therapeutic work. Although there is a prevalent caricature of the psychoanalyst, and to a lesser degree of the psychoanalytic psychotherapist, as working in a withholding and aloof fashion, the concepts of optimal frustration and optimal gratification imply that there is a position held by the psychiatrist that is neither sterile nor overstimulating and that promotes the establishment of a meaningful therapeutic relationship.

The rule of free association, often referred to as the "basic rule," dictates that the patient's primary obligation within the psychoanalytic situation is that of verbalizing, to the best of her or his ability, without editing, whatever comes into awareness, including thoughts, feelings, physical sensations, memories, dreams, fears, wishes, fantasies, and perceptions of the analyst. This rule is relevant to psychoanalytic psychotherapy as well. Whereas at first glance this requirement appears to be unscientific, in fact, the psychiatrist and patient quickly come to appreciate that no thought or feeling is random or irrelevant but rather that all mental content is relevant to the patient's emotional problems. Indeed, much productive therapeutic work is focused on those instances when the patient is not able to speak what is on his or her mind. As an example, a patient suddenly stops talking after enthusiastically reporting the recent achievements of her son. In response to the therapist's asking what is making it difficult to continue, the patient at first states that her mind is blank and then apologizes for "bragging." Further exploration reveals the fear of the therapist's jealousy and resentment of her child's possibly outperforming the therapist's children.

Dream interpretation has been a significant feature of psychoanalysis since the turn of the century. Many psychoanalytic psychotherapists also use this technique, although recently there may be less emphasis on this. Freud placed great emphasis on the interpretation of dreams not only because it was pivotal in his self-analysis but also because he discovered that such a technique provided insights into the working of the unconscious. In a similar fashion, slips of the tongue, jokes, puns, and some types of forgetfulness are attended to carefully by the therapist because they are nonsleep activities that also provide insight into the patient's unconscious mental processes. Good technique does not necessarily include pointing out to the patient these events each time they occur, for they may often be a source of intense embarrassment. Rather, the slips are noted as helpful data in assessing the patient's inner thoughts.

All of these techniques are embedded in a unique manner of listening to the patient's verbalizations within the context of the treatment situation. In particular, two related but specific components initially attributed to the analyst's listening process are worthy of note. First, the concept of the analyst's evenly hovering or evenly suspended attention implies that listening to the patient requires of the analyst that he or she be nonjudgmental and give equal attention to every topic and detail that the patient provides. This rule is relevant to psychoanalytic psychotherapy as well. Whereas at first glance this requirement appears to be unscientific, in fact, the psychiatrist and patient quickly come to appreciate that no thought or feeling is random or irrelevant but rather that all mental content is relevant to the patient's emotional problems. understood, as well as provides the therapist with a method to achieve vicarious introspection. Indeed, one of the major contributions of self psychology has been the identification of empathic listening and interpretation (the immersion by the therapist into the subjectivity of the patient’s experience) as basic to the methodology of psychoanalysis and psychoanalytic psychotherapy (Kohut 1978, 1971). Interferences to successful empathic listening are often the product of countertransference reactions, which should be suspected whenever, for example, the therapist experiences irritation, strong erotic feelings, or inattention during a treatment session.

**How Does Psychoanalytic Psychotherapy Work?**

Classical psychoanalysis has held that patients are helped by the acquisition of insight into their intrapsychic conflicts. More specifically, conflict is resolved through precise and accurate transference interpretations, which eventually permit the patient to experience the analyst with fewer distortions from childhood experiences. From a structural point of view, the outcome of this interpretive process is a strengthening of the ego and often a softening of the superego. From a different vantage point, it could be said that psychoanalysis helps by permitting the patient to become increasingly conscious of troublesome feelings, conflicts, and wishes that heretofore had remained out of awareness and that produced unhappiness by promoting repetitive self-defeating behaviors.

Whereas insight has always been valued as a goal of psychoanalysis, insight by itself is insufficient. The process whereby insight is acquired is a lengthy and arduous one that is inextricably linked with the recall of painful affects, memories, and traumatic experiences. For treatment to be effective, there must be then both cognitive and affective experiences for the patient. Neither a purely intellectual nor a purely cathartic experience is likely to result in relief or behavioral change. The support provided by the treatment relationship, which includes commitment, respect, reliability, honesty, and care, is a powerful factor in the mutative or “curative” process. It is this atmosphere that makes bearable the emotional pain that accompanies the healing of the wounds first experienced in isolation, so often inflicted by the first objects of the patient’s love, need, and trust. All of these considerations are central to psychoanalytic psychotherapy as well.

The concept of “working through” is helpful in appreciating the lengthy and complex psychoanalytic and psychotherapeutic processes. Working through is that stage or aspect of treatment characterized by repeated identification of reenactment and reliving of earlier experiences through confrontation, clarification, and interpretation of resistance and transference that ultimately promote the patient’s self-awareness. In effect, the working through process frees the patient from the position of being at the mercy of unconscious conflicts and fears that have compromised interpersonal relationships and achievement. This is accomplished not only through the analysis of the transference but also of current interpersonal relationships outside of the analysis or psychotherapy. Ultimately, a thorough understanding of the transference and of current relationships permits the patient to appreciate their relationship to important early experiences and to ameliorate the influence of the past on the present.

**Therapeutic Alliance**

The “curative” process as first conceptualized in psychoanalysis rested on the analyst’s strict interpretation of intrapsychic conflicts as manifested within the transference neurosis. Accurate transference interpretations ultimately permitted the patient to appreciate the limiting or self-defeating distortions in her or his current life that more appropriately resided in early childhood perceptions. Currently, psychoanalysis places greater importance on the role of the therapeutic or working alliance than was previously emphasized (Zetzel 1956, Greenson 1967). Both of these terms relate to the real component, as distinguished from the transference component, of the therapist–patient relationship. The real component is composed of the patient’s conscious, rational, and nonconflictual feelings toward the therapist that permit a collaborative relationship and that provide the motivation for working toward symptom relief.

A great deal of research in the outcome of psychoanalytic psychotherapy has focused on the importance of the therapeutic alliance (Docherty 1985). Increasing appreciation for the role of supportive factors, such as the rapport between the patient and therapist that constitutes the therapeutic relationship, has balanced the earlier and more narrowly defined position that attributed therapeutic success exclusively to insight resulting from the analyst’s specific interpretive activity. The clinical consequences of this appreciation of the helpfulness of nonspecific factors have been the psychoanalytic psychotherapist’s paying much greater attention to the initial phases of engaging the patient in psychotherapy and a greater respect for those positive and negative factors that the therapist brings to the working relationship. More specifically, earlier psychoanalysis was more likely to understand the patient’s responses and attitudes toward the analyst as products exclusively of transference distortions. Currently, psychoanalysis and psychoanalytic psychotherapy hold that the psychiatrist’s personality and interventional technique have equal influence on the therapeutic process. In essence, the contemporary view is more dyadic, and places greater importance on the contributions of the therapist (both the conscious and the unconscious), as well as of the patient with respect to progress and impasse in the psychotherapeutic process.

It is important to note, however, that there is strong call for reassessment of the specificity of the role of the therapeutic alliance. Clinicians and researchers alike have argued that the concept of therapeutic alliance must be more clearly defined in terms of the distinct attributes that contribute to positive outcome (Horvath 2006, Meissner 2006, Castonguay et al. 2006, Crites-Christoph et al. 2006, Hatcher and Barends 2006). As examples, Horvath argues for a clearer definition of the alliance in research and how it shifts throughout phases of treatment. Meissner, a psychoanalyst, argues that the confusion in the concept of the therapeutic alliance lies in the blurred boundaries of the three components of the alliance, namely, transference, working alliance, and the real relationship. Both Horvath and Meissner agree on the need for a greater pantheoretical and theory specific appreciation.
Indications for Psychoanalysis

Drives

Freud’s psychoanalytic model of the mind continually changed throughout his career. His first conceptualization was based on an id psychology, which directed the analyst to attend to the patient’s hidden sexual and aggressive drives in the form of wishes, needs, and impulses as conceptualized within the topographic point of view. His second model, ego psychology, focused more on bringing to the patient’s awareness both repressed and disavowed mental content and the role of the unconscious defense mechanisms of the ego as it mediated conflict. Early psychoanalysis then focused on the analysis of drives; later psychoanalysis emphasized drives and their defenses. Analysis based on the later model had limitations as well, especially when the patient did not have a typical symptom neurosis but rather had more characterological problems. It is fair to say that today many psychoanalysts and psychoanalytic psychotherapists attribute less importance to the concept of drives.

Interpersonal and Object Relationships

One significant clinical and theoretical revision that attempted to transcend the limitations of ego psychology was object relations theory. As with many facets of psychoanalytic theory, object relations theory is not unitary. Some emphasize the quality of interpersonal relations and yet others emphasize how psychic structure is built through the process of internalization. Object relations theory focuses on early organizing experiences with others that not only constitute an important component of the self but also influence the manner in which a person experiences himself or herself and others throughout life. Some object relationists retained drive theory (Jacobson 1964, Kernberg 1975, Mahler et al. 1975) whereas others did not (Sullivan 1953, Guntrip 1971). All, however, gave greater credence to the role of internalized object relations both in normal development and in psychiatric illness. Integrating “good and bad objects” was considered the goal of normal development, whereas psychiatric illness resulted when these objects remained separate or “split.”

Others (Kohut 1978, Sullivan 1953) thought that object relations theory did not effectively close the gap between theory and practice, especially with respect to the treatment of severe personality disorders. Self psychology deleted the drives as a central organizing principle and raised the development of self-esteem to a supraordinate theoretical and clinical position. Although the contributions of self psychology have been debated for the last 35 years, much of self psychology has now become a part of modern psychoanalysis and psychoanalytic psychotherapy. This is especially true regarding the importance of empathy in treatment, as well as the appreciation of the so-called self-object transference configurations: the idealizing transference, twinship transference, and the mirror transference. (See Chapter 28 for a more in-depth appreciation of both object relations and self psychology.)

In summary, contemporary psychoanalysis and psychoanalytic psychotherapy still emphasize elucidation of the unconscious, especially within the transference, and still use interpretation as the primary clinical intervention but recognize more fully the important role of the mutual emotional engagement of therapist and patient and the curative role of this relationship in addition to other supportive factors. They adhere to a much broader perspective on human development and psychiatric disorders. Psychological problems can result not only from early intrapsychic conflict but also from developmental deficits or failures as well as from psychological trauma (Table 87–7).

Clinical Vignette 5 is a segment of process from the third year of a 4.5-year psychotherapy conducted by a woman therapist illustrating the following:

- Free association.
- Working alliance (threats to and the reestablishment of).
- Transference perceptions and reactions based on experiences both with mother and with father.
- Defense and resistance, including denial, projection, reaction formation, and acting out.
- Failure of defenses, manifested by symptoms of anxiety, depression, and somatization.
- Use of confrontation, clarification, and interpretation of wishes and impulses, defenses, and resistances.
- Dream interpretation.
- Genetic reconstruction.
- Role of neutrality and abstinence in maintaining the safety requisite to the patient’s experiencing and expressing highly charged, previously unconscious wishes and fears.
- Development of insight, accompanied by a decrease in symptoms.
Ms. J began treatment at age 35 because of anxiety, work inhibitions, and a tendency to “martyr” herself. She also wanted help with her highly ambivalent relationships of 15 years with her husband and of 8 of those years with her married lover. Ms. J had been subjected to chronic verbal, physical, and sexual abuse by her alcoholic father throughout her childhood. Her mother, depressed and overburdened with many children, was hurtful primarily in her collusive blindness to the father’s predations.

Two months before the therapist’s planned summer vacation, the patient terminated her sexual involvement with her lover. She became increasingly ambivalent about this decision as the interruption approached. She imagined that her therapist (1) valued men more than women and felt that a man’s wishes should always be gratified, (2) found her needs burdensome and preferred that she turn to her lover for the attention she wanted, and (3) was going on vacation to punish her for refusing sex. On the other hand, the patient felt that the therapist was possessive of her attention and did not want her to resume the affair with her lover (projection). The patient recognized that her anger about the therapist’s attention to her own family and the resulting jealous wish for retaliation (passive into active) had also played a role in her renewed interest in the extramarital love affair. Together, the patient and therapist understood these feelings and ideas (transference) as aspects of the patient’s reexperiencing, within the treatment, the relationship with the mother of her childhood who had left her to the father, fostering the incest and who had sometimes given more attention to her siblings.

Moreover, the patient felt that the therapist was possessive of her attention and did not want her to resume the affair. The patient experienced the therapist as withholding attention from her during the vacation, preferring to be with others as her father had sometimes preferred to be with the mother or siblings. The patient recognized that her own angry jealousy of the therapist’s family and the wish for retaliation against the therapist played a role in her renewed interest in the extramarital involvement.

During the first psychotherapy session after the vacation, Ms. J reported that as soon as the therapist had left town, she had lost interest in understanding her feelings before acting on them and had resumed her sexual affair (acting out). She soon stopped the sexual involvement when she realized having experienced an insight: she had felt hurt, inappropriately she thought, when her husband did not want her to touch him. She linked this reaction to her fear of the therapist’s rejection because of her sexual behavior during the vacation. She also talked about having “needs that you are unwilling to meet” (neutrality and abstinence). Whereas she had felt last month that the affair was a harmless way of having needs met that were “not being met elsewhere” (displacement), she now stated ambiguously that by “not choosing between the relationships” she was “putting a ceiling on things.” The therapist better understood the resistance function of the sexual acting out: it had discharged unconscious sexual impulses in relation to the therapist that were threatening, both because of fears of disapproval and of gratification of those wishes through action. That is, the patient was trying to prevent the therapist from responding sexually as the father had done in her childhood. Putting a ceiling on things seemed to be the patient’s attempt to keep things safe, to keep the therapist under control. Testing this hypothesis, the therapist asked, “Might the affair be putting a ceiling on things here with me as well?” The patient stated that it would be dangerous to want or ask more of the therapist because of the risk of rejection and punishment. Also, although getting attention from her lover was “illegitimate, it was less wrong than getting it from you would be. Part of it is sexual,” she said, and went on to discuss the role her lover played as mentor and advisor.

Confronting what was being resisted, the therapist asked the patient, “What about the sexual part?” The patient talked about the “infantile part,” wanting to be rocked and held by the therapist, and went on to label her physical needs and desires as “excessive, bad, something that should be repressed.” In an attempt to interpret the patient’s wishes that were as yet unacknowledged (resistance), the therapist addressed both impulse and defense. The therapist used the somewhat ambiguous action word from the patient’s statement at the start of the hour, saying, “It’s uncomfortable, threatening when you’re aware of wanting me to touch you, then.” The patient acknowledged that because the psychotherapeutic relationship did not include physical contact, she turned to the sexual affair to have those needs met (displacement). Interpreting the defense, the therapist said, “When you find it threatening to want me to meet that need sexually, you find it safer to return to your lover.” “Yes. It protects both of us. I see it as a threat to the relationship. It might ruin things.” The therapist interpreted more specifically the patient’s fear of her own desires: “I think that you’re feeling that the desire might ruin things not only because I might disapprove, but also because you’re afraid there will be some actual behavior that would ruin things.” The patient agreed. “That’s right. I think I’m afraid the desire would lead to behavior. When I was a child, other ways weren’t found to deal with things. I think the desire makes me afraid you’ll become my father” (transference and genetic reconstruction).

The next day the patient reported that during the latter part of this hour she had been experiencing back pain (an example of somatization as a failure of defenses), a symptom that throughout the psychotherapy accompanied memories of past sexual abuse. The pain, anxiety, and depression she had been feeling the day before had dissipated after the hour (insight accompanied by decrease in symptoms).
How Does Psychoanalytic Psychotherapy Differ from Psychoanalysis?

The answer to this question has occupied many researchers and psychiatrists throughout the previous and current centuries. Efforts have been made continually not only to elucidate the differences between the two treatments but also, more importantly, to define the underlying principles of psychoanalytic psychotherapy. Whereas some prefer definitions of psychoanalysis and psychotherapy as distinct, separate entities, it is more useful to many psychiatrists to conceptualize psychoanalysis and psychoanalytic psychotherapy as residing on a therapeutic continuum. As discussed, there is much in the conduct of psychoanalytic psychotherapy that has been borrowed from psychoanalysis. Free association, clarification, and interpretation in psychoanalytic psychotherapy are such examples. The centrality of transference is another, although early psychiatrists and researchers advocated that transferences were to be recognized and acknowledged in psychoanalytic psychotherapy and "managed" rather than interpreted so that patients were not subject to the intense therapeutic regressions characteristic of psychoanalysis. Today, such a distinction regarding the approach to transference in psychoanalytic psychotherapy is less rigid.

On the other hand, certain supportive and more directive techniques, such as greater activity of the therapist through focusing the patient on specific current problems and relationships, reassuring and affirming the patient, and the giving of advice, are used much more in psychoanalytic psychotherapy than in psychoanalysis. Therefore, the adherence to the therapist's neutrality is less strict, and as a result, there is often but not always less frustration for the patient in psychoanalytic psychotherapy.

The answer to this question has occupied many researchers and psychiatrists throughout the previous and current centuries. Efforts have been made continually not only to elucidate the differences between the two treatments but also, more importantly, to define the underlying principles of psychoanalytic psychotherapy. Whereas some prefer definitions of psychoanalysis and psychotherapy as distinct, separate entities, it is more useful to many psychiatrists to conceptualize psychoanalysis and psychoanalytic psychotherapy as residing on a therapeutic continuum. As discussed, there is much in the conduct of psychoanalytic psychotherapy that has been borrowed from psychoanalysis. Free association, clarification, and interpretation in psychoanalytic psychotherapy are such examples. The centrality of transference is another, although early psychiatrists and researchers advocated that transferences were to be recognized and acknowledged in psychoanalytic psychotherapy and "managed" rather than interpreted so that patients were not subject to the intense therapeutic regressions characteristic of psychoanalysis. Today, such a distinction regarding the approach to transference in psychoanalytic psychotherapy is less rigid.

On the other hand, certain supportive and more directive techniques, such as greater activity of the therapist through focusing the patient on specific current problems and relationships, reassuring and affirming the patient, and the giving of advice, are used much more in psychoanalytic psychotherapy than in psychoanalysis. Therefore, the adherence to the therapist's neutrality is less strict, and as a result, there is often but not always less frustration for the patient in psychoanalytic psychotherapy. The length of treatment may not distinguish the two approaches, but the frequency of sessions (four or five per week) and the use of the couch, however, are characteristic of psychoanalysis.

Overall, it is fair to say that psychoanalytic psychotherapy has the following characteristics:

- It places greater emphasis on the here and now in terms of the patient's current interpersonal relationships and experiences outside of the therapy; whereas in psychoanalysis, there is greater emphasis on the experiences within the analysis and the relationship between analyst and analysand.
- It incorporates, more than does psychoanalysis, various other techniques from other dynamic and behavioral psychotherapies.
- It emphasizes the usefulness of focusing on current (dynamic) problems and less on genetic issues.
- It establishes more modest goals of treatment.

The last point is particularly important in that it facilitated the development of brief dynamic psychotherapies that address focal problems generally in up to 20 sessions.

Tasks of the Psychoanalytic Psychotherapist

What are the challenges of the psychotherapist in performing psychoanalytic psychotherapy? First, the therapist must ensure that the patient feels both emotionally and physically safe within the therapeutic relationship. This is accomplished by acknowledging the goals of the treatment and defining the role of the therapist and through establishing professional boundaries. Boundaries refer to those constant and highly predictable components of the treatment situation that constitute the framework of the working relationship. For example, agreeing to meet with the patient for a specified amount of time, in a professional office, and for an established fee are some of the elements of the professional framework. Boundaries also have ethical dimensions best summarized as the absolute adherence by the therapist to the rule of never taking advantage of the patient: through sexual behavior; for personal, financial, or emotional gain; or by exploiting the patient's need and love for the therapist in any fashion (e.g., by using the therapy sessions to discuss the therapist's own problems). The concepts of neutrality, abstinence, and confidentiality further define the role of the therapist. (See Chapter 5 for more discussion of frame, boundaries.)

A critical task of the psychoanalytic psychotherapist is to detect when a breach in either role or boundary has occurred and to restore the patient's security through clarifying and interpreting the meaningfulness of such a breach. As an example, a patient and a therapist were suddenly interrupted in their session by hospital maintenance personnel who obtained entry into the office through the use of a master key. After dismissing the workers, the therapist observed that the patient became uncharacteristically silent. The therapist acknowledged the unanticipated disruption and its impact on the patient, and requested that the patient share what he was thinking during and after the intrusion. The patient told of the effects of a childhood incident in which his bathroom privacy was violated by a distant family member.

The explication of a boundary violation is but one specific example of the technique of interpretation. Successful interpretation is based on a number of prerequisite skills. These include the capacity to empathize with the patient's plight, the ability to recognize the meaning of one's own fantasies about, and responses to, a patient (countertransference), the ability to maintain the patient's verbal flow through the use of open-ended or focused questions, and the capacity to tolerate a relatively high level of ambiguity within the therapeutic relationship. One important professional characteristic of the skilled psychotherapist is patience. Psychotherapy is often arduous, and the capacity to "stay in the chair" with the patient particularly when patients express strong affects is critical.

The identification of repeated patterns of behavior both within the therapy and in the patient's outside life is a fundamental technique in making sense of the patient's emotional life. This, of course, involves the appreciation of transference and the art of knowing how and when to share this recognition with the patient. Interpretation relies on both appropriate timing and dosage. That is, the psychoanalytic psychotherapist must appreciate when the patient can best integrate the therapist's observations and must respect the patient's defenses, taking care not to overwhelm the patient by insisting that she or he confront more than is tolerable. A poor interpretation is exemplified by Clinical Vignette 6.
Psychoanalytic psychotherapy requires the successful engagement of the patient and the establishment of a therapeutic or working alliance. The alliance can be threatened by a number of phenomena including, but not limited to, the following:

- The therapist’s countertransferences or other limitations in his or her capacity to tolerate the emotions stirred by the patient, resulting in empathic failures and mistakes.
- The emergence of intense feelings and needs within the patient, for example, when an accurate, well-timed intervention evokes feelings in relation to the therapist of appreciation and love accompanied by feelings of vulnerability, erotic desire, or inferiority, which the patient wants to flee.
- The patient’s being reminded of the existence of others in the therapist’s life, such as other patients or family (e.g., during interruptions due to the therapist’s vacations), triggering painful and embarrassing feelings of jealousy and possessiveness.

The therapist’s ability to appreciate and respectfully acknowledge to the patient the impact of these temporal events is critical to the progress of treatment.

From another vantage point, the therapist must also be able to “pass the test” (Weiss 1993). That is, in addition to transference reactions, patients may turn the passive into active by replicating within the therapeutic relationship the original conflictual, disappointing, or traumatic parental experience but reversing the roles. Essentially, the patient does to the psychotherapist what was initially done to her or him. For example, a patient whose parents never seemed to have time to listen has the habit of ending the session 2 minutes early to avoid feeling interrupted and rejected. Such behavior is an adaptive, largely unconscious, interpersonal strategy whose objective is to assess the level of safety within the therapeutic dyad and ultimately to master a psychological problem. If the psychotherapist can pass the test, that is, responds differently from the patient’s early negative childhood expectations or pathogenic beliefs, the patient feels more secure and can allow deepening of the therapeutic process. Clinical Vignette 7 illustrates this concept of passing the test, a central component of control–mastery theory (Weiss 1995).

All of the psychotherapist’s skills and techniques must be embedded in a consistent and coherent theoretical viewpoint that provides the therapist with a framework to understand the etiology and meaning of a patient’s symptoms and dysfunctional behaviors both in the past and in the present in each of the phases of psychotherapy (Table 87–8). This includes an organized method for understanding the therapist’s unconscious and conscious responses to the patient as well. It requires that the therapist listen to the patient’s communications in a manner that is markedly different from other forms of social discourse. So-called “process communication” speaks to the therapist on multiple levels and through displacement, through passing remarks and jokes, through shifts in topics, and through metaphors and symbols. To assist in understanding complicated process communication, psychiatrists often ask themselves: Why is the patient telling me this now? What might the patient be trying to say about his or her uncomfortable feelings? Is something being said about the therapeutic relationship? To illustrate, a patient begins the session by being angry about a bill he received for a medical procedure that had not alleviated his physical symptoms. Its high cost and ineffectiveness seem to reflect the physician’s uncaring attitude and willingness to make money at the patient’s expense. The therapist asks whether the patient recently received his bill for the psychotherapy and could his concerns about the physician apply to his psychotherapy relationship as well.
As noted, psychoanalytic psychotherapy differs from psychoanalysis in its weight given to the use of supportive measures and in the establishment of more circumscribed goals. Both the psychoanalytic psychotherapist and the psychoanalyst must be skillful in supporting the patient at times of emotional disequilibrium but they may differ in the degree and manner in which support is provided to the patient. Psychoanalysis has always striven for an extensive transformation of the patient’s characterological problems and a thorough analysis of the patient’s transference neurosis. The psychoanalytic psychotherapist must be skillful in setting more limited goals with a patient regarding the reconstruction of the patient’s past. The objective of this type of treatment is to improve the patient’s quality of life largely through enhancing interpersonal relationships by promoting greater insights into perceptual distortion and intrapsychic and interpersonal conflict. Psychoanalytic psychotherapy accomplishes this objective by focusing much more on the patient’s current predicaments as manifested in both life activities and relationship with the therapist. Compared with psychoanalysis, it is often, but not always, less concerned with the analysis of transference and the complete discovery of the underlying genetic precursors of the patient’s current psychological problems.

**Indications for Psychoanalytic Psychotherapy**

Although current psychotherapy research attempts to ascertain what specific disorder in what type of patient is most effectively treated by what specific psychotherapeutic approach, studies have not as yet provided the answers to these questions. At this time, it is possible only to speak in generalities based on case reports and limited studies. Conditions and disorders for which psychoanalytic psychotherapy appears to be indicated include Clusters B&C personality disorders (except antisocial personality disorder), acute and posttraumatic stress disorders, symptom neuroses or neurotic conflicts, adjustment disorders, paraphilias, and some mood, anxiety, somatoform, sexual and gender identity, eating, substance abuse, and dissociative disorders (Table 87–9). In addition, psychoanalytic psychotherapy is often employed in treating patients who present with relational problems and those problems that are the result of abuse or neglect. It may also be useful to patients with certain impulse disorders and to patients whose psychological problems are affecting or are the result of their primary medical illnesses. Subthreshold disorders, it must be remembered, may be accompanied by significant psychic pain. In this regard, psychoanalytic psychotherapy is helpful to those who are challenged by intimacy with and commitment to others as well as those suffering from longstanding grief, and those not meeting criteria for Cluster B&C personality disorders but nevertheless are troubled by self-defeating behavior. In short, psychoanalytic psychotherapy, often in combination with medication, is an appropriate intervention in a broad range of disorders, conditions, and psychiatric illnesses (Karasu 1989, Gabbard 1995).

With increasing frequency, patients who are suitable for psychoanalysis are treated in psychoanalytic psychotherapy because of extrinsic demands such as financial resources, time limitations, and job and family conflicts. The characteristics of the patient assumed to be correlated with positive outcome in psychoanalytic psychotherapy include introspectiveness (psychological mindedness or wish to understand the meaningfulness of behaviors and their relationship with feeling and thoughts), ability to establish and maintain human relationships, even “unhealthy” ones, vocational stability, high degree of motivation, absence of formal thought disorder, and psychological resources sufficient to withstand the frustration of the treatment and its characteristic therapeutic regression and accompanying strong affects.

**Contraindications to Psychoanalytic Psychotherapy**

Although it is no longer the case, psychoanalytic psychotherapy had been traditionally reserved for patients who could not tolerate the inherent frustration and therapeutic regression of psychoanalysis. More often than not, the issue of analyzability (roughly comparable to treatability) was framed in terms of the assessment of the patient’s ego strengths. If a patient was thought to have insufficient psychological resources to withstand the rigors of a psychoanalysis, especially a patient with severe personality disorders and significant thought disorders, psychoanalytic psychotherapy might be prescribed. Similarly, if the patient was considered to be poorly motivated or had some cognitive deficit that might prevent the integration of interpretations, she or he was urged toward a treatment with more supportive elements. For the most part, contraindications to any psychoanalytic psychotherapy that is heavily weighted toward the expressive end of the therapeutic continuum are as follows (Table 87–10):

Supportive Psychoanalytic Psychotherapy

Although only recently systematized, this form of psychotherapy provides psychological stabilization to the patient through the vehicle of a consistent and predictable caring therapist–patient relationship (Werman 1984, Rockland 1989, Novalis et al. 1993, Hellerstein et al. 1994, Misch 2000). The provision of emotional support to patients with psychiatric disorders can be traced to the 18th-century moral treatment movement advocated by Pinel and others. Supportive psychotherapy attempts to shore up the patient’s defenses and enhance his or her ability to cope with the trials of illness or psychological deficits and the challenges they impose on the patient’s daily activities (Table 87–11). Not unexpectedly, it also strives to prevent decompensation and regression. As such, psychoanalytic supportive psychotherapy employs a psychodynamic understanding of the patient’s difficulties but does not emphasize interpretation of the patient’s internal world. Rather, supportive psychotherapy focuses on assisting the patient to address interpersonal and environmental challenges in the here and now.

Despite its noninterpretive emphasis, supportive psychotherapy can have substantial impact in the lives of patients with significant ego deficits and those with major mental illness. These patients may include those with high levels of aggressivity, poor impulse control, overreliance on action rather than verbal expression of emotions, compromised reality testing, and limited psychological mindedness. It is also highly effective with higher functioning patients who have experienced recent psychic trauma (e.g., through natural disasters, illness, physical or sexual assault, and unexpected devastating losses).

Supportive psychotherapy techniques consist predominantly of empathically listening to the patient’s feelings and experiences, giving advice and reassurance, offering suggestion and helpful coping techniques, and for some patients with severe and chronic maladaptations, gently revealing their misperceptions and how they interfere in daily functioning. Although often unexpressed, the patient’s identification with the therapist’s values, ideals, and approaches to problems is exceptionally therapeutic. Environmental interventions through helping agencies and the patient’s significant others are also effective supportive techniques. Although nonspecific to some degree, these interventions are nevertheless based on a comprehensive understanding of the patient’s strengths and weaknesses, and are frequently instrumental in curbing self-destructive and self-defeating behaviors. Transference is appreciated but the therapist rarely interprets it in supportive psychoanalytic psychotherapy, choosing rather to foster a positive working relationship through other means (Pinsker et al. 1992).

Although frequently disparaged, effective supportive psychoanalytic psychotherapy is often more challenging to provide than some forms of expressive psychotherapy. Appreciating the psychological forces that are impinging on a marginally functioning patient whose communicative abilities are suboptimal requires a sophisticated clinical approach. Moreover, in supportive psychotherapy, the therapist must assist the patient to modulate intense affective states that are often frightening to the patient and to those in his or her environment. Needless to say, such affects can be directed at the therapist as well. The establishment of the requisite safe and caring relationship with the patient, which may be frequently disrupted by both internal and external forces, is often a significant clinical challenge.

Supportive psychotherapy can produce significant and lasting behavioral change through the reinforcement of health-promoting behaviors, increased capacity for self-reflection, anxiety reduction, and development of new defenses such as intellectualization that enable the patient to acquire a cognitive, anxiety-reducing conceptualization of her or his difficulties.
Gender Issues in Psychotherapy

Does the gender of the psychotherapist have any effect on the psychotherapeutic relationship and treatment outcome? Are certain psychological problems best treated by therapists whose gender is different from that of the patient? Do different phenomena appear in the treatment of those patients whose therapists are of the same gender? Is the duration of treatment affected by the therapist’s gender? Does gender have any influence on the choice of therapist by a patient? These are important questions that have been debated in psychotherapy and psychoanalytic literature for more than 50 years.

The influence of the therapist’s gender on the treatment relationship was first raised by Freud in 1931 (reprinted in Freud 1961), who suggested that women analysts might have the ability to promote a greater variety of transferences than their male counterparts. Shortly thereafter, Thompson (1939) articulated what has become of the traditional psychoanalytic psychotherapeutic position regarding the gender of the therapist, namely, that the therapist’s personality is much more critical to the treatment outcome than is his or her gender. A classic study of sex role stereotypical beliefs held by psychotherapists (psychiatrists, social workers, and psychologists) demonstrated that psychological health was defined in terms of normative development for men, whereas for women alone, dimensions such as emotional lability, submissiveness, and dependency were denoted as healthy (Broverman et al. 1970). Although the existence of some influence of such attitudes on the therapy is intuitively compelling, studies examining actual behavior of the therapist rather than beliefs and attitudes do not conclusively demonstrate that gender stereotyping of the therapist has direct effects on the treatment process, length of treatment, or outcome (Schwartz and Abromowitz 1975, Abromowitz et al. 1976, Blasé 1979, Orlinsky and Howard 1976). Women psychotherapists, however, do have an advantage over their male counterparts in terms of satisfaction for both female and male patients (Kirshner et al. 1978).

Although the literature regarding the advantages and disadvantages of gender matching of patients and therapists consists largely of anecdotal and negative reports (Zlotnick et al. 1998), it is nevertheless evocative. A number of common themes have emerged, including the following:

- The gender of the therapist may be more critical in supportive treatments that rely on identification with the therapist (Cavenar and Werman 1983).
- The therapist’s gender may be less important in psychoanalysis than in face-to-face psychoanalytic psychotherapies, because in the latter the transference can be less intense (Mogul 1982).
- Beginning women therapists have less difficulty with empathy but more difficulty with authority issues than do their male counterparts (Kaplan 1979).

The wish for a woman to be treated by a female psychotherapist, an increasingly common event, may be related to a number of different issues. For example, the woman may wish to rectify an unfulfilling experience with her own mother, seek permission from another woman to be assertive and accomplished, anticipate feelings understood more readily by another woman than by a man, or feel greater physical safety in the therapeutic relationship with another woman, particularly if she has experienced past sexual abuse or has been the victim of sexual misconduct by a previous male therapist.

Similarly, a woman might choose a male therapist if she is fearful of becoming dependent on another woman (Nadelson and Notman 1991). A female psychotherapist could also be valued in the early portion of therapy but then subsequently be devalued as the female patient begins to experience the therapist competitively (Notman et al. 1978) or as other more hostile transferences unfold.

Male patients can have comparable conscious and unconscious reasons for selecting a psychotherapist by gender. For instance, men who are frightened of male competition or intense homosexual concerns might gravitate toward female psychotherapists. Men who have been unsuccessful in establishing meaningful relationships with women might select a female therapist in the hope that she could teach him how to be successful with women. The same might be true for a male patient suffering from sexual dysfunction who yearns for the secret of what sexually pleases women. Conversely, a man fearful of strong women, a man hungry for a strong male figure with whom he can identify, or a man seeking to avoid dependent or strong heterosexual feelings in the treatment relationship might prefer a male therapist. Although therapists are accustomed to operating in an increasingly androgynous world, female therapists may be surprised to encounter stronger resistance in treating “traditional” male patients in settings such as veterans administration hospitals (Deering and Gannon 2005, Good 2005).

In short, although there is only one controlled study and it showed no difference regarding the influence of the therapist’s gender on the therapeutic process (Zlotnick et al. 1996), there is much to consider about the influence of actual gender and gender-related beliefs of both patient and therapist on the emergence of transference and countertransference. However, the best psychoanalytic psychotherapies will include ample opportunities for the working through of the patient’s issues related to important figures of both genders.

Ethnocultural Issues in Psychotherapy

Culture refers to meanings, values, and behavioral norms that are learned and transmitted in the dominant society and within its social groups. Culture powerfully influences cognitions, feeling, and “self” concept, as well as the diagnostic process and treatment decisions. Ethnicity, a related concept, refers to social groupings that distinguish themselves from other groups based on ideas of shared descent and aspirations, as well as to behavioral norms and forms of personal identity associated with such groups (Mezzich et al. 1993).

The DSM-IV-TR advocates for the importance of ethnic and cultural considerations through a cultural formulation that augments the multiaxial diagnostic assessment of culturally diverse patients (American Psychiatric Association 1994). The cultural formulation is derived from the traditional biopsychosocial case formulation, and it emphasizes how culture may influence the expression of symptoms, the patient’s conceptualization of illness, the treatment, and
the treating relationship (Mezzich et al. 1993). The guidelines for cultural formulation that served as the template for the DSM-IV-TR outline are presented in Table 87–12.

<table>
<thead>
<tr>
<th>Table 87–12</th>
<th>Guidelines for Cultural Formulation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Area</td>
<td>Summary</td>
</tr>
<tr>
<td>Cultural identity of the individual</td>
<td>The clinician should specify the individual’s cultural reference groups. Attend particularly to language abilities, use, and preferences (including multilingualism). For immigrants and ethnic minorities, note separately the degree of involvement with both the culture of origin and the host or majority culture.</td>
</tr>
<tr>
<td>Cultural explanations of the individual’s illness</td>
<td>Identify (1) the predominant idioms of distress through which symptoms are communicated (e.g., “nerves,” possessing spirits, somatic complaints, inexplicable misfortune), (2) the meaning and perceived severity of the individual’s symptoms in relation to norms of the cultural reference group, (3) any local illness category used by the individual’s family and community to identify the condition, (4) the perceived causes or explanatory models that the individual and the reference group employ to explain the illness, and (5) current preferences and past experience with professional and popular sources of care.</td>
</tr>
<tr>
<td>Cultural factors related to psychosocial environment and functioning</td>
<td>Note culturally relevant interpretations of social stressors, available social supports, and levels of functioning and disability. Special attention should be given to stresses in the local social environment and to the role of religion and kin networks in providing emotional, instrumental, and informational support.</td>
</tr>
<tr>
<td>Cultural elements of the relationship between the individual and the clinician</td>
<td>Indicate differences in culture and social status between the individual and the clinician and problems that these differences may cause in diagnosis and treatment (e.g., difficulty in communicating in the individual’s first language, in eliciting symptoms or understanding their cultural significance, in negotiating an appropriate relationship or level of intimacy, in determining whether a behavior is normative or pathological).</td>
</tr>
<tr>
<td>Overall cultural assessment for diagnosis and care</td>
<td>The formulation should conclude with a discussion of how these cultural considerations specifically influence comprehensive diagnosis and care.</td>
</tr>

Source: Mezzich et al. (1993).

In the establishment of a therapeutic alliance, the patient’s cultural difference from the therapist may add another level of complexity to the therapeutic process. For example, in engaging a Japanese patient, the psychotherapist must be cognizant of the patient’s need for formality because an informal style may lead to embarrassment for the patient (Marsella 1989). In the treatment of some Asian patients, there may be an inherent cultural expectation that the therapist teach the patient how to correct her or his behavior (Blue and Gonzalez 1992). The ability to trust the psychotherapist is a fundamental task of any psychotherapy. Establishing trust with an African-American patient, for example, may be more complicated for a white psychotherapist if the patient’s experiences with the dominant culture or white physicians have been disappointing or demeaning. An African-American psychotherapist might have to encounter early in the treatment overt or covert prejudice from a white patient. A Native American patient may have great distrust for a white therapist who represents a dominant culture. In some circumstances, a patient from a different culture might be obsequious in an attempt to please the psychotherapist.

Comas-Diaz and Jacobsen (1991, 2001) have introduced the concept of ethnocultural allodynia to describe an intense sensitivity and response to relatively innocuous or neutral stimuli emanating from previous culturally based painful experiences. They describe how sociocultural and ethnic emotional injuries can have profound impact on self-cohesiveness and object relationships. As is the case in Herman’s concept of complex posttraumatic stress disorder (PTSD) (Herman 1992), alterations in self-perception and perception of others, affective lability, interpersonal relationships, world view, and hope can accompany traumatic ethnocultural experiences that, when present, require attention within the treatment relationship (Comas-Diaz and Jacobsen 2001).

Countertransference reactions, too, may be influenced by the patient’s culture. For example, novice psychotherapists often become so intrigued by the culturally diverse patient that they behave as if they were clinical anthropologists and neglect the patient’s emotional pain by focusing exclusively on the patient’s culture (Comas-Diaz and Jacobsen 1991). For other therapists, the struggle with impulses to right historical or sociological wrongs may be expressed in persistent rescue feelings. Under certain circumstances, when culturally diverse therapists treat patients from their own culture, they may distance themselves from their patients or may overidentify with them.

Given the increasing multiculturalism of many cities in the United States, how should the psychoanalytic psychotherapist treat patients from cultures other than his or her own? Whereas therapists are obligated to be culturally informed, Foulks et al. (1995) have argued against the promotion of culturally specific psychotherapies. Although acknowledging that some cross-cultural psychiatrists believe expressive–supportive psychotherapy to be an ethnotherapy appropriate only to the citizens of the Western world, they emphasized the overwhelming problems in establishing separate therapies and clinics devoted to patients from a multitude of specific cultures. Also, they stated that the principles of psychotherapy elucidated in this chapter—accepting, understanding, and explaining—are appropriate for the culturally diverse patient.
Is Psychoanalytic Psychotherapy Effective?
The short answer to this question is yes. The longer answer would require an extensive chapter on the history of psychotherapy research (Talley et al. 1994, Wallerstein 1995).

The effectiveness of psychotherapies was first challenged by the argument that responses to psychotherapeutic treatment were no greater than those achieved through spontaneous remission (Eysenck 1952). Many studies have criticized this finding, the latest of which was based on a reevaluation of Eysenck’s (McNeilly and Howard 1991) original data, which demonstrated that approximately 15 sessions of psychotherapy can accomplish the same result as a spontaneous remission that takes 2 years. Meta-analytical studies of psychotherapy have demonstrated unequivocally that psychotherapy is effective (Luborsky et al. 1975, Smith et al. 1980, Lambert et al. 1986). The study by Smith et al. (1980), for example, demonstrated that 80% of those patients treated in psychotherapy fared better on outcome measures than those who received no treatment. Psychological growth achieved through psychotherapy is also enduring (Husby 1985).

The helpfulness of psychotherapy for those patients suffering from significant medical illness has been documented. Spiegel et al. (1989) demonstrated that breast cancer patients enrolled in expressive–supportive group psychotherapy lived an average of 18 months longer than control subjects who were not treated with group therapy. A more recent study of the effect of group psychotherapy on survival of patients with metastatic breast cancer, however, failed to replicate prolonged survival but did note that women receiving supportive–expressive psychotherapy had significant improvement in mood and pain perception particularly in those subjects who were initially more distressed (Goodwin et al. 2001).

Similarly, patients with lymphoma, leukemia, and malignant melanoma fared better with their illnesses when treated with supportive individual and group interventions (Richardson et al. 1990, Fawzy et al. 1993). Expressive–supportive psychotherapy is also effective in opioid-dependent patients attending community methadone maintenance programs and is superior to counseling (Woody et al. 1995).

Other cost-offset studies have repeatedly demonstrated the helpfulness of psychotherapy in reducing general health care services by as much as one-third (Mumford et al. 1984, Krupnick and Pincus 1992, Olfson and Pincus 1994). These include reduction in hospital stays for surgical and cardiac patients (Mumford et al. 1982) and decreased treatment costs for those with respiratory illnesses, diabetes, and hypertension (Schlesinger et al. 1983). Brief psychotherapy has also been shown to be effective in general medical clinics, where those patients with significant medical and psychiatric problems improve substantially more than those treated by primary care physicians alone (Meyer et al. 1981).

Whereas earlier meta-analyses addressed psychoanalytic, cognitive, and behavioral therapies as an aggregate, Luborsky et al. (1993) have demonstrated that psychoanalytic psychotherapy is as effective as cognitive, behavioral, experiential, and group therapies and hypnotherapy. For this meta-analysis, rigorous inclusion criteria were established including, but not limited to, adequate sample size with random assignment, suitable length and frequency of sessions, sound outcome measures, adherence by therapists to treatment manuals, and comparable skill levels among therapists.

Milrod et al. (2001) have demonstrated the usefulness of their manualized brief psychodynamic psychotherapy in the treatment of panic disorder. In this open trial, 21 patients on no medication received twice weekly therapy for 24 sessions. Sixteen of the 17 subjects who completed treatment experienced remission of panic and agoraphobic symptoms. Eighty-one percent of patients had a comorbid disorder and those with depression also improved dramatically. In addition, improvements in quality of life were significant and were sustained at 6-month follow-up. More recently, Milrod et al. (2007) reported on their RCT of this treatment of 49 patients. Both the psychodynamic treatment group and the comparison group in this study (applied relaxation training) received twice weekly sessions for 12 weeks. Patients who were treated with psychodynamic psychotherapy had significantly greater reduction in panic symptoms and were significantly more likely to respond at treatment termination (73% vs. 39%). This was true of psychosocial functioning as well.

Transference-focused psychotherapy (TFP) is a manualized twice weekly psychodynamic psychotherapy of 1 year or longer duration for treating those with borderline personality disorder (Clarkin et al. 1999). It attempts to reduce self-defeating and self-destructive behavior and borderline symptomatology through the appreciation and modification of self and others as they are manifested within the treatment relationship. Levy et al. (2006) reported the results from an RCT of 90 patients treated with TFP, dialectical behavior therapy (DBT), and a modified psychodynamic psychotherapy. Because many of the symptoms of borderline personality disorder can best be understood from an attachment theory perspective, this study examined attachment patterns and reflective function (RF) in subjects before and after 12 months of treatment. After 1 year of treatment with TFP, but not with DBT and supportive psychotherapy, participants demonstrated a significant increase in higher order attachment state (secure attachment). Significant changes in narrative coherence (presentation of a balanced and realistic view of attachment relationships) and RF were found in the TFP group. RF is a measurement of mentalization that describes the acquisition of the capacity to make sense of behavior in oneself and in others and thereby appreciating thoughts, feelings, and beliefs of others (Fonagy et al. 2002). This study, however, failed to find any differences between the three treatments regarding resolution of trauma and loss both of which are intimately related to poor attachment styles.

A study of brief psychodynamic psychotherapy in patients with panic disorder combined with medication demonstrated that combined treatment was superior to medication alone (Wolfberg and Dahl 1996). In this comparative study, subjects were treated with either clomipramine or 15 sessions of dynamic psychotherapy with clomipramine. After discontinuation of medication at 9 months, the relapse rate for those treated with medication alone was significantly higher. Those treated with combined treatment functioned at higher levels, which was attributed to the gains made in psychotherapy.

A randomized controlled study of psychoanalytic psychotherapy and medication versus standard psychiatric care (which included no psychotherapy) in the treatment of 44 patients with borderline personality disorder demonstrated
the effectiveness of psychoanalytic psychotherapy (Bateman and Fonagy 2001). At 18-month follow-up, those who had received psychotherapy in the context of a partial hospital program of a year and a half not only maintained their improvement in functioning but also demonstrated increased gains in a number of significant domains while receiving ongoing twice weekly psychoanalytic group psychotherapy. These gains included fewer suicide attempts, less self-mutilating behavior, a lower number and shorter duration of inpatient admissions, and less use of other psychiatric services. There was also continued symptomatic improvement in anxiety, depression, and general symptom distress, as well as gains in interpersonal relationships and social adjustment.

Swiss researchers (Burnand et al. 2002) conducted a randomized controlled trial of combined psychodynamic psychotherapy and clomipramine in the outpatient treatment of major depression. Seventy-four patients with major depression received either 10 sessions of psychodynamic psychotherapy with medication or medication and supportive psychotherapy. Those in the former group were treated by nurses who received 6 months of training, followed a manualized protocol, and were supervised weekly by an experienced psychoanalyst. While both treatment groups demonstrated significant improvement, medication plus dynamic psychotherapy was associated with both better work and higher global functioning. Moreover, in the psychodynamic psychotherapy treatment group there were fewer treatment failures and posttreatment hospitalizations, which resulted in cost savings (direct and indirect costs) of $2,311 per patient. For those patients who were employed at the onset of the study, savings amounted to $3,394 in indirect costs.

Svartberg et al. (2004) conducted a randomized controlled study of the effectiveness of short-term dynamic psychotherapy (STDP) of 40 sessions and CBT for 50 Cluster C personality disordered patients. Assessments were performed at the outset, midway of treatment, and follow-up at 2 years. Changes in symptom distress were noted for those patients treated with STDP but not with CBT. Forty percent of both groups improved with respect to interpersonal problems and personality functioning. At 2 years, 54% of the those treated with STDP and 42% of those treated with CBT improved symptomatically. Subjects continued to improve after termination supporting a central concept in brief treatment that the effects of treatment often grow with time.

Leichsenrig and colleagues have published a number of important rigorous meta-analytic studies recently. They compared psychodynamic psychotherapy (14 studies) with CBT (11 studies) in the treatment of personality disorders (Leichsenrig and Leibling 2003). Only those studies were considered that employed standardized measures to assess psychopathology, utilized reliable and valid outcome measures, and yielded data allowing calculation of within-group effect sizes. Analysis of the studies demonstrated a large overall effect size (1.46) for dynamic therapy with effect sizes of 1.08 and 1.79 for self-report measures and observed-rated measures respectively. For CBT, the corresponding values were 1.0, 1.2, and 0.87. For psychotherapy studies, effect sizes are characterized as weak (0.2), moderate (0.5), and robust (0.8). An effect size of 1.0 corresponds to a success rate of 72%. This meta-analysis indicated, moreover, that long-term changes with dynamic treatment were achieved.

A larger second study (Leichsenrig et al. 2004a, 2004b) of the efficacy of short-term psychodynamic psychotherapy (STPP) examined 17 studies (Table 87–13) with the following inclusion criteria:

- Randomized controlled design
- Specific forms of STPP (manualized or manual like with treatment integrity assured)
- Trained and experienced therapists
- Specific disorders treated
- Reliability and outcome measures
- Sufficient data to determine pre- and posttreatment effects.

Results of the study indicated the following gains that were better than treatment as usual or using a waiting list as a control:

- Improvement in target problems (effect size 1.39).
- Improvement in general psychiatric symptoms (effect size 0.990).
- Improvement in social functioning (effect size 0.80).
- At follow-up, effect sizes were stable and corresponded to 1.57, 0.95, and 1.19 respectively.
- Ninety-two percent of patients are better off regarding their target problems with treatment.
- Follow-up at the average of 13 months after treatment showed 95% were better off after termination.
- Seventy-five percent of studies included in the meta-analysis were not included in previous meta-analyses, and interpersonal psychotherapy (IPT) studies were excluded since IPT is not a psychodynamic therapy and its presence in earlier studies have skewed results.

(For a more complete list of psychodynamic psychotherapy studies, many of which were not included in this second study, see Leichsenrig et al. 2006.)

The most recent Cochrane Database of Systematic Reviews of STDPs examined 23 studies of 1,431 randomized patients with common mental disorders for general, somatic, anxiety, and depressive symptom reduction. Psychosocial adjustment was a component of the review as well. This review concluded that outcomes for most categories suggested significantly greater improvement in the treatment groups compared to control groups and that gains were maintained in medium- and long-term follow-up. Limitations were noted regarding the small number and heterogeneity of studies as well as variability in treatment quality (Abbass et al. 2006).

At this time, however, the therapist is left with few data supporting the superiority of one type of psychotherapy over another for a given condition or disorder (Smith et al. 1980). This dilemma must be tempered by the recognition of the enormous complexity of psychotherapy research. The important research questions with respect to brief psychoanalytic psychotherapy have been summarized by Barber (1994) and are relevant to all psychoanalytic psychotherapies (Table 87–14).

Source: Modified from Leichsenring et al. (2004b).
Abbreviations: APT, adaptive psychotherapy; ART, applied relaxation training; BT, behavioral therapy; CBT, cognitive behavioral therapy; DBT, dialectical behavior therapy; DC, drug counseling; HT, hypnotherapy; IPT, interpersonal therapy; NDC, nondirective counseling; PTSD, posttraumatic stress disorder; SPT, supportive psychoanalytic therapy; ST, supportive therapy; STPP, short-term psychodynamic psychotherapy; TAU, treatment as usual; TFP, transference-focused psychotherapy.
*As suggested by one of the anonymous reviewers, manual-guided DC was regarded as a form of psychotherapy rather than TAU.

The majority of studies examining psychoanalysis and psychoanalytic psychotherapy have been outcome studies rather than comparative. Although many early outcome studies of psychoanalysis were methodologically unsound (Wallerstein 1995), a number of these that examined both outcome and therapeutic process were sophisticated (Bachrach et al. 1991). In general, process studies have attempted to examine important variables, such as how interpretation and therapeutic alliance are related to outcome and how transference, central conflict, and internalization...
are measured in a reliable and valid manner (Barber 1994). The Menninger Psychotherapy Research Project, for example, attempted to answer not only outcome (what changes accrued from treatment) but also how such changes were brought about in those patients receiving psychoanalysis, psychoanalytic psychotherapy, and supportive psychoanalytic psychotherapy (Wallerstein 1986). The psychotherapy research project’s most significant findings centered on the unanticipated effectiveness of supportive psychoanalytic psychotherapy in the treatment of patients with significant psychiatric illness. In short, across all three forms of psychoanalytic psychotherapy, changes emanating from supportive interventions were substantial and in no way inferior to the more expressive interventions of psychoanalysis that were aimed at structural change. Similarly, a recent study by Hoglend et al. (2006) demonstrated that patients with poor object relations profited more from therapy employing transference interpretations than from therapy without transference interpretations.

Long-Term versus Brief Psychotherapies
Despite the massive economic forces impinging on the current practice of long-term psychoanalytic psychotherapies, both brief and extended expressive and supportive treatments are required in the psychiatrist’s therapeutic armamentarium. Whereas the research on brief psychoanalytic psychotherapies has been impressive, patients successfully treated by these techniques have generally met inclusion criteria that place them in the less dysfunctional range of psychiatric illness; that is, they tend to have less severe character disorder. Moreover, more than 80% of patients entering psychoanalysis have previously been unsuccessful in less intensive forms of treatment (Doidge et al. 1994). Up to 25% of all depressed patients do not tolerate medications or they respond poorly to them (American Psychiatric Association 1993), and of course there are always patients who will not agree to take antidepressants. Even the National Institute of Mental Health Collaborative Study of Depression, which assessed cognitive–behavioral therapy and IPT and tricyclic antidepressant medication, demonstrated the exceptional efficacy of psychotherapy. Shea et al. (1992) have argued that 16 weeks of treatment appears to be insufficient for many patients to achieve a full recovery. The need for maintenance psychotherapy in treating unipolar depression has been substantiated (Frank et al. 1990). A significant study of the relationship between the number of sessions and patient improvement in psychotherapy has shown that by 8 sessions and 26 sessions of weekly psychotherapy 50 and 75% of patients, respectively, improve (Howard et al. 1986). When chronic distress and characterological symptoms are examined, however, 74–89% of patients with chronic distress and only 60% of patients with character problems improve after a year of treatment (Kopta et al. 1992). In short, patients with more complex conditions often require longer treatment.

Disconnection between Psychotherapy Practice and Research
There is a persistent tension in the psychotherapy research literature relating to the perception that therapists do not integrate the findings from psychotherapy research and that psychotherapy researchers fail to study the relevant clinical issues (Stiles 1992). From the therapist’s point of view, most psychotherapy research lacks a therapeutic context and fails to answer basic questions such as the following: How is a treatment altered when the patient has unusual characteristics? What intervention should the therapist use if the prescribed treatment is failing? How should therapeutic change be assessed? (See Westen et al. (2004) for a more complete discussion of the limitations of evidence based psychotherapy.) The tension between therapists and researchers has been made all the more strident because of pressures placed on both parties to prove cost-effectiveness for all psychotherapeutic interventions. Unfortunately, nationally funded research in psychotherapy has not been a priority, and when such research is funded, more often than not, it must embrace a clinical trials methodology, which may or may not be able to ask the relevant clinical questions.

What can be done about bridging the chasm between psychotherapy practice and research? Talley et al. (1994) have advocated five practices likely to be helpful in creating a rapprochement between researchers and therapists. First, case studies should no longer be disparaged, for they have the ability to be scientifically rigorous by testing specific hypotheses. Second, wherever possible, researchers should endeavor to include clinical vignettes in their published work and emphasize the clinical applicability of specific findings. Third, studies must be conducted that determine what type of psychotherapy research is helpful to therapists. Fourth, the accessibility of psychotherapy research findings to therapists should be studied with respect to knowledge of new findings as well as understandability. Last, training programs must assist students to integrate new research findings, as well as train a new generation of researchers to ask the clinically significant questions.

Toward a Neurobiology of Psychotherapy
Exciting new research in psychiatry, brain imaging, cognitive neuroscience, genetics, and molecular biology has provided striking insights into how psychotherapy actually changes both brain structure and function (Liggan and Kay 1999, Gabbard 2000, Lehrer and Kay 2002, Etkin et al. 2005). Learning and memory are associated with alterations in central nervous system (CNS) neuronal plasticity including increased synaptic strength and number of synapses. Neureogenesis, or the creation of new brain cells, occurs daily in the human hippocampus (Eriksson et al. 1998), the central
location for the formation of new explicit memories. Not only does memory consolidation lead to persistent modification in synaptic plasticity, but psychotherapy, a form of learning, also produces changes in the permanent storage of information acquired throughout an individual’s life and provides new resources to address important psychobiological relationships between affect, attachment, and memory, which is of fundamental importance in psychiatric disorders. Rapidly accruing knowledge about the different types of memory and the role of the amygdala now support the influence of memories that reside outside of the awareness of our patients (LeDoux 1996). Implicit memories formed in infancy and childhood persistently affect the manner in which patients experience themselves and their worlds as manifested, for example, in transference reactions within and outside of the therapeutic relationship.

Research beginning in the last decade has demonstrated that psychotherapy affects cerebral metabolic rates. Two studies have provided preliminary evidence that psychoanalytic psychotherapy alters serotonin metabolism in borderline personality disorder and depression (Vinamaki et al. 1998, Saarinen et al. 2005). Comparative imaging studies testing nonpsychoanalytic psychotherapy versus medication have shown equally normalizing changes in regional cerebral blood flow (rCBF) and neurotransmitter metabolism in patients with obsessive-compulsive disorder (OCD; Baxter et al. 1992) and major depression (Baxter et al. 1992, Brody et al. 2001, Martin et al. 2001, Goldapple et al. 2004) as well as in social phobia (Furmark et al. 2002). Goldapple’s study, however, was the first to note similar but also differential changes between psychotherapy and medication. A recent study by Kennedy et al. (2007) also found differential effects between psychotherapy and medication. Other studies have shown restoration of sleep architecture and thyroid hormone levels after psychotherapeutic treatment of patients with major depression (Thase et al. 1998, Joffe et al. 1996) (Table 87–15).

Psychotherapy may have profound impact on neuroimmunology. As noted, providing psychotherapy to patients who have metastatic breast cancer or malignant melanoma can reduce morbidity and perhaps mortality (Spiegel et al. 1989, Fawzy et al. 1993). Elucidating the role of the hypothalamic–pituitary–adrenal system (HPA axis) has also clarified the impact of stress on learning, memory, and lifelong psychological adaptation during important periods of attachment in mammals (Suomi 1991, Rosenblum and Andrews 1994, Kaufman et al. 2000). Many studies have demonstrated enduring elevated levels of cortisol, adrenocorticotropic hormone, and corticotrophin-releasing factor following episodes of maternal separation. Even with appropriate substitute nurturing, animals respond to stress in a more intense fashion throughout their lives. Early experiences therefore can have profound impact on future psychosocial and neurobiological development as has been demonstrated in reduced hippocampal volumes of children who have experienced abuse and maltreatment (Bremner et al. 1997).

Last, genetic and epidemiological studies have clarified the role of experiences on gene expression and vulnerability to psychiatric illness. Kendler’s large study of groups of female twins, both at low and high risk for major depression, eloquently demonstrated that the meaning and valence of a stressor have great influence on illness onset (Kendler et al. 1995). The probability for depression for low-risk twins and high-risk twins who experienced a recent death, assault, or marital problems increased from 0.5 to 6.2% and 1.1 to 14.6% respectively, over a 17-month period. A more recent study by Kendler et al. (2005) addressed the interaction of stressful life events and 5HTT (serotonin transporter) polymorphism in the prediction of major depression. Another study examined the gene–environment interaction by elucidating that children with low monoamine oxidase A (MAOA) and who experienced maltreatment were more likely to have significant antisocial behavior compared to children with abuse but not low MAOA (Caspi et al. 2002).

Similarly, by studying large numbers of teenagers from variously configured families, Reiss demonstrated that the inherited psychological and temperamental characteristics of children can evoke very different types of relatedness from their parents (Reiss et al. 1995). Compared to their siblings, teenagers who had highly conflictual relationships with their parents, for example, a negative way of relating, accounted for nearly two-thirds of variance in antisocial behavior and more than one-third the variance in depressive symptomatology. The experience of a nonshared family environment expressed by the differential treatment of adolescents has significant explanatory power as to why some are at greater risk for mental illness.

The study of psychotherapy from a neurobiological perspective is likely to provide greater understanding of how words in the context of therapeutic relationships can heal. It may be that there are similar mechanisms and anatomical regions that are involved in the successful treatment of psychiatric illness with psychotherapy and pharmacotherapy as monotherapies, as well as in the combined treatment situation (Sachem 2001). It is also likely to yield a greater understanding of pathogenesis and delineate helpful interventions to decrease genetic vulnerability to emotional disorders. The ability to predict the outcome of treatment with psychotherapy and medication will undoubtedly be available in the near future (Mayberg et al. 1997).

Conclusion
The practice of psychoanalytic psychotherapy by psychiatrists is currently under scrutiny. Nevertheless, the majority of all encounters with patients in American psychiatry involve some form of psychotherapy, and many of these interventions are based on the principles of psychoanalytic psychotherapy.

At this time, the theory and technique of psychoanalytic psychotherapy provide the most comprehensive orientation to the continuum of expressive–supportive psychotherapy. Psychoanalytic psychotherapy is a potent intervention and, as such, holds great promise when it is used in a sophisticated fashion for appropriate patients with appropriate psychiatric problems. Like medication, psychoanalytic psychotherapy has specific indications, contraindications, and undoubtedly, potentially negative effects. As an effective therapeutic intervention, it requires that the therapist be highly skilled in assessing the inner experience of those who come for help. It also requires extensive training and education in techniques of this treatment modality. In addition, the therapist must acquire significant self-knowledge, sophistication, and dedication in working so intensively with human pain.

Introduction
In the 1970s, the late Gerald L. Klerman, M.D., Myrna M. Weissman, Ph.D., Bruce Rounsaville, and Eve Chevron (1984) developed a psychotherapy based on life events and social functioning to use in an antidepressant medication trial. What became known as interpersonal psychotherapy (IPT) is a time-limited, diagnosis-focused therapy has subsequently been tested in numerous randomized controlled clinical trials. Research has established its efficacy as an acute and chronic treatment for patients with major depressive disorder (MDD), and as an acute treatment for bulimia nervosa. Other outcome studies have suggested its promise for other psychiatric diagnoses, such as anxiety disorders, and its lack of efficacy for patients with substance use disorders. The research findings have led to its inclusion in treatment guidelines and increasing dissemination into clinical practice.

IPT is a straightforward, manual-based, focused, pragmatic, and optimistic time-limited psychotherapy. It has been best tested as a treatment of major depressive episodes (MDEs), on which this chapter will focus. IPT has two basic premises. First, depression is a medical illness, which is treatable and not the patient’s fault. Second, the disorder does not occur in a vacuum, but rather is influenced by and itself affects the patient’s psychosocial environment. Changes in relationships or other life events may precipitate depressive episodes in individuals vulnerable to depression; conversely, depressive episodes strain relationships and provoke negative life events. The goal of treatment is to help the patient solve a crisis in his or her role functioning or social environment. Achieving this helps the patient to gain a sense of mastery over his or her functioning and relieves depressive symptoms. Given its clinical focus on interpersonal functioning, it is unsurprising that IPT has been shown to build social skills. (See Table 88–1.)

IPT was defined in a manual (Klerman et al. 1984, updated by Weissman et al. 2000, 2007). Demonstration of efficacy in research trials for patients with MDEs led to its adaptation and testing for other mood and nonmood disorders. This has included modification for adolescent and geriatric depressed patients, patients with bipolar and dysthymic disorders, depressed HIV-positive and depressed pregnant and postpartum patients, and depressed primary care patients. Most of the modifications have been relatively slight, retaining the general principles and techniques of IPT for major depression. Nonmood targets have included bulimia, substance abuse, borderline personality disorder, and several anxiety disorders. IPT has also been adapted as a maintenance treatment to forestall relapse and recurrence of depressive episodes, for couples and group formats, as a telephone intervention, and in a patient self-help guide (Weissman et al. 2000, 2007). Begun as a research intervention, IPT has begun to spread among clinicians and in residency training programs. The publication of efficacy data and the promulgation of practice guidelines that embrace IPT among antidepressant treatments have led to increasing demand for IPT training. Managed care and economic pressures have aroused interest in defined, time-limited, empirically supported treatments like IPT. Practice guidelines for mental health professionals (Karasu et al. 1993) and primary care practitioners (Depression Guideline Panel 1993, Vols 1–4) cited IPT as an acute and maintenance treatment for depression, used alone and in combination with medication.

American Psychiatric Association practice guidelines for adults with major depression included IPT among the few recommended psychotherapies. IPT was deemed useful for patients in the “midst of recent conflicts with significant others and for those having difficulty adjusting to an altered career or social role or other life transition” (Karasu et al. 1993, p 6); that is, for depression associated with life events or interpersonal conflicts. Although many patients present with such recent life changes, the empirical support for IPT among depressed patients generally makes these appear minimal, conservative indications.

Both the physician and patient guides in primary care guidelines for depression (Depression Guideline Panel 1993) list IPT, cognitive–behavioral therapy (CBT; Beck et al. 1979), behavioral, brief dynamic, and marital therapy as treatments for depression. The guidelines recommend IPT as an acute treatment for nonpsychotic depression, to remove symptoms, prevent relapse and recurrence, correct

proving psychological problems with secondary symptom resolution, and address secondary consequences of depression. The guidelines note that medication alone may suffice to prevent relapse or recurrence, and to maintain remitted patients with recurrent depression (cf. Frank et al. 1990, 1991). These guidelines consider IPT, CBT, and behavioral treatments “effective in most cases of mild-to-moderate depression” (Depression Guideline Panel 1993, Vol. 2, p 12) but indications “for continuation phase psychotherapy are unclear” (Depression Guideline Panel 1993, p 18) even though “two studies are suggestive that continuation psychotherapy may reduce the relapse rate” (Depression Guideline Panel 1993, p 18). The Patient Guidelines list behavioral, cognitive, and IPT as the “most well-studied [sic] for their effectiveness in reducing symptoms of major depressive disorder” (Depression Guideline Panel 1993, Vol. 4, p 23).

IPT is spreading from its initial research base in the United States. The IPT manual has been translated into Italian, German, Japanese, Spanish, and French, and is being used more widely around the world. Descriptions of IPT have appeared in Spanish (Puig 1995) and Dutch journals (Blom et al. 1996). An International Society for Interpersonal Psychotherapy (www.interpersonalpsychotherapy.org), established at the American Psychiatric Association Annual meeting in May 2000 in Chicago, has a growing membership and held international scientific meetings in 2004 and 2006.

That IPT has not been included among the psychotherapies required for “competency” in American residency training programs reflects a shortage of trained supervisors rather than lack of evidence of efficacy. Indeed, more evidence supports the utility of IPT than of any of the mandated psychotherapies save CBT.

(For a complete description of IPT technique, see Weissman et al. [2000] or [2007]; for the patient guide, see Weissman [1995]. For the group adaptation, see Willley et al. [2000]; for depressed adolescents, see Mufson et al. [2004a]; for dysthymic disorder, see Markowitz [1998]; for bipolar disorder, see Frank [2005].)

Background

IPT is based on the interpersonal theory of Adolph Meyer, Harry Stack Sullivan (1953), and later John Bowlby (1973) and others. (See Table 88–2.) The principle derived from these theories is that life events occurring after the early childhood years influence psychopathology. Social supports protect against psychopathology, whereas social losses may trigger symptoms in vulnerable individuals. IPT employs this principle for practical, not etiological, purposes. It does not presume to discern the cause of a depressive episode—assuming the etiology of depression to be multifactorial—but pragmatically uses the connection between current life events and the onset of depressive symptoms to help the patient understand and combat the episode of illness. IPT is also based on psychosocial and life events research of depression, which demonstrated relationships between depression and complicated bereavement, role disputes (e.g., bad marriages), role transitions (meaningful life changes), and interpersonal deficits (social isolation).

Conducting IPT

IPT therapists define depression as a medical illness, a treatable condition that is not the patient’s fault. This definition displaces burdensome guilt from the patient herself to the illness, making the symptoms ego-dystonic and discrete. It also provides hope for a response to treatment. The therapist uses the DSM-IV-TR (American Psychiatric Association 2000) to diagnose the patient, and rating scales such as the Hamilton Depression Rating Scale (HDRS; Hamilton 1960) or Beck Depression Inventory (BDI; Beck 1978) to assess and explain the depressive symptoms. This process begins psychoeducation, helping the patient to recognize that the problem is a common mood disorder with a predictable set of symptoms, not the personal failure, weakness, or character flaw that the depressed patient often believes to be the issue.

Underscoring this approach, IPT therapists give depressed patients the “sick role” (Parsons 1951), temporarily excusing them from what their illness prevents them from doing while obliging them to work as patients in order to recover the healthy role they have lost. The sick role does not encourage disability, as some therapists may fear. Instead, it helps the patient to see how depression interferes with functioning, shifting blame from the guilty patient to the depression itself for this disability, and raising the expectation that functioning will improve as the depression recedes. The resolution of the sick role is to regain the healthy, euthymic role by the end of treatment.

The time-limited structure of IPT also energizes patients and protects against regression during treatment. By solving an interpersonal crisis—a complicated bereavement, a role dispute or transition, or an interpersonal deficit—the IPT patient has the dual opportunity to improve his or her life situation and simultaneously relieve the symptoms of the depressive episode. This coupled formula, validated by randomized controlled trials in which IPT has been tested, can be offered with confidence and
optimism. Symptomatic relief may correlate with the degree to which the patient solves his or her interpersonal crisis (Markowitz et al. 2006a). This therapeutic optimism, while hardly specific to IPT, very likely provides part of its power in remoralizing the patient. (See Table 88–3.)

It is not its specific techniques but its overall strategies that make IPT a unique and coherent approach. An eclectic therapy, IPT uses techniques seen in other treatment approaches. For example, the medical model of depressive illness IPT employs is consistent with pharmacotherapy (making it highly compatible in combination with medication). IPT shares role playing and a “here and now” focus with CBT, and addresses interpersonal issues in a manner familiar to marital therapists. Although like CBT a time-limited treatment targeting a syndromal constellation (e.g., major depression), IPT is considerably less structured, assigns no explicit homework, and focuses on interpersonal problem areas rather than automatic thoughts. IPT overlaps to some degree with psychodynamic psychotherapies, and many of its early research therapists came from psychodynamic backgrounds. Yet IPT also meaningfully differs from them: in its focus on the present, not the past; its focus on practical, real life change rather than self-understanding; its medical model; and its avoidance of the transference and of genetic and dream interpretations (Markowitz et al. 1998a).

Each of the four IPT interpersonal problem areas has discrete, if partially overlapping, goals for therapist and patient to pursue. The therapist helps the patient relate life events to mood and other symptoms. Techniques include an opening question, which elicits an interval history of mood and events, communication analysis, the reconstruction and evaluation of recent, affectively charged life circumstances, exploration of the patient’s wishes and options, in order to pursue these in particular interpersonal situations, decision analysis, to help the patient choose which options to employ, and role playing, to help patients rehearse tactics for real life.

IPT deals with current rather than past interpersonal relationships, focusing on the patient’s immediate social context. The IPT therapist attempts to intervene in depressive symptom formation and social dysfunction rather than addressing enduring aspects of personality. Personality is in fact difficult to accurately assess during an episode of an Axis I disorder such as major depression (Hirschfeld et al. 1983). IPT does build new social skills such as self-assertion and the effective use of anger (Weissman et al. 1981), which may be as valuable as changing personality traits. One study found that maintenance IPT for recurrent depression reduced Axis II Cluster C symptoms over time (Cyranowski et al. 2004).

**Phases of Treatment**

As an acute treatment, IPT has three phases. The first phase, lasting from one to no more than three sessions, includes diagnostic evaluation, psychiatric anamnesis, and setting the treatment framework. The therapist reviews symptoms, diagnoses the patient as depressed by standard criteria (APA 2000), and gives the patient the sick role (Parsons 1951). The psychiatric history includes the “interpersonal inventory,” which is not a structured instrument but a careful review of the patient’s past and current social functioning and close relationships, their patterns and mutual expectations. How does this patient relate to other people? This evaluatory interview elucidates changes in relationships surrounding the onset of symptoms; for example, death of a loved one, children leaving home, worsening marital strife, or isolation from a confidant. This review provides a framework for understanding the social and interpersonal context of the onset of depressive symptoms and the basis for a treatment focus.

Having assessed the need for medication based on symptom severity, prior treatment response, and patient preference, the therapist educates the patient about depression by discussing the constellation of emotional, cognitive, and physical symptoms that define major depression, their psychosocial concomitants, and what the patient may expect from treatment. The therapist next links the depressive syndrome to the patient’s interpersonal situation in a formulation (Markowitz and Swartz 1997) focusing on one of four interpersonal problem areas: (1) grief; (2) interpersonal role disputes; (3) role transitions; or (4) interpersonal deficits. Once the patient explicitly accepts this formulation as the focus for treatment, IPT enters its middle phase.

It is important to keep treatment focused on a simple theme that even a highly distracted depressed patient can grasp. Any formulation necessarily simplifies a patient’s life narrative. Although some patients may present with multiple interpersonal problems, the goal of the formulation is to
isolate one or, at most, two salient problems related to the patient's mood disorder (whether as precipitant or consequence). More than two foci would mean no focus at all. The choice of focal problem area depends on clinical acumen, although research has shown that IPT therapists agree in choosing such areas (Markowitz et al. 2000), and patients find the foci credible.

During the opening phase the therapist also sets a time limit for the acute treatment, generally between 12 and 16 sessions. The optimal number of sessions for IPT requires further research; one study suggests that as few as eight sessions may be effective for some patients (Swartz et al. 2004). Sessions are scheduled weekly: this allows sufficient time to pass that things will happen in the patient's outside life, on which the treatment focuses, yet is frequent enough to maintain momentum and thematic continuity.

The middle phase involves strategies specific to the chosen interpersonal problem area. For grief—complicated bereavement following the death of a loved one—the therapist facilitates the catharsis of mourning and helps the patient find new activities and relationships to compensate for the loss. Role disputes are conflicts with significant others: a spouse, other family member, boss, coworker, or close friend. The therapist helps the patient explore the relationship, the nature of the dispute, whether it has reached an impasse, and available options to negotiate its resolution. If these options fail, therapist and patient may conclude that the relationship has reached an impasse and consider ways to change the impasse or to end the relationship. Role transition includes change in life status; for example, beginning or ending a relationship or career, moving, promotion, demotion, retirement, graduation, having a baby, or diagnosis of a(nother) medical illness. The patient learns to manage the change by mourning the loss of the old role, recognizing positive and negative aspects of the new role he or she is assuming, and taking steps to master the new role.

Interpersonal deficits, the poorly named, residual fourth IPT problem area, is used for patients who lack one of the first three problem areas; that is, patients who report no recent life events. This focus defines the patient as isolated and lacking social skills, including having problems in initiating or sustaining relationships; the goal is to help the patient to develop new relationships and skills. Some patients who fall into this category may in fact suffer from dysthymic disorder, for which separate strategies have been developed (Markowitz 1998).

IPT sessions address present “here and now” problems rather than childhood or developmental issues. They focus on affect and interpersonal behaviors rather than cognitions. Sessions open with the question, “How have things been since we last met?” This focuses the patient on recent interpersonal events and recent mood, which the therapist helps the patient to link. Therapists take an active, nonneutral, supportive, and hopeful stance to counter the depressed patient’s pessimism. They elicit and emphasize the options that exist for change in the patient’s life, options that the depressive episode may have kept the patient from seeing or exploring fully. Nor does understanding the situation suffice: therapists stress the need for patients to test these options in order to improve their lives and simultaneously treat their depressive episodes. Over the course of therapy, the IPT therapist regularly repeats measurements such as the HDRS so that both therapist and patient can gauge the latter’s progress.

The final phase of IPT, occupying the last few sessions of acute treatment or last months of maintenance treatment, builds the patient’s newly regained sense of independence and competence by recognizing and consolidating therapeutic gains. The therapist underscores the patient’s competence to function without further therapy by emphasizing that the depressive episode has improved because of the patient’s actions in changing a life situation—and this at a time when the patient had felt weak and impotent. The therapist also helps the patient to anticipate triggers for and responses to depressive symptoms that might arise in the future. Compared to psychodynamic psychotherapy, IPT de-emphasizes termination: it is a bittersweet graduation from successful treatment. The sadness of parting from the therapist is contrasted with depressive feelings. If the patient has not improved, the therapist emphasizes that the treatment has failed, not the patient, and that alternative effective treatment options exist. Patients with multiple prior MDEs or significant residual symptoms, who successfully complete acute treatment but remain at high risk for recurrence, may contract for maintenance therapy as acute treatment draws to a close.

Clinical Vignette

Ms. A, a 42-year-old married lawyer, presented with a 6-month history of major depression and a baseline 24-item HDRS score of 27. Her symptoms included a depressed and anxious mood with diurnal variation, early and middle insomnia, fatigue, difficulty concentrating, indecisiveness, and the feeling that life was not worth living. She had no plan and had made no suicide attempts; she denied psychotic symptoms and substance abuse. Although she initially described her symptoms without linking them to a context, her therapist took a careful history and connected the depressive episode to recent life events. Ms. A’s symptoms coincided with her worsening relationship with her lawyer husband. She felt he had become increasingly distant, and might be having an affair.

Ms. A had had an episode of depression 12 years before that had resolved with a course of antidepressant medication; she had stopped the medication after about 9 months. Four years before that, she had had 6 months of evidently supportive psychotherapy to address her anxiety about marrying her husband; she had found talking helpful at the time, and had decided to marry. Her family history was notable for maternal depression. Her interpersonal inventory revealed that she had few close friends, in whom she was more likely to confide than her husband. She counted on her mother for support, feeling distanced from a strict and unemotional father and a somewhat sadistic brother.

Ms. A was deferential to her husband, who worked at a smaller and less prestigious law firm and was easily angered. In retrospect, she felt that their marriage had worsened after they had been unable to conceive a child and had gone for infertility treatment in her mid-30s. Her husband had initially blamed her for their difficulties, but since his low sperm count and motility had been identified as the problem, he had sulkily withdrawn from the relationship, and often slept in the living room. He kept ever longer working hours, and Ms. A worried that he might be having an affair. They had rarely discussed their feelings, however, and she felt he would explode with anger if she dared to confront him.
Ms. A declined to take antidepressant medication, as her previous serotonin reuptake inhibitor trial had made her “jumpy” and inhibited her libido—the last thing she now felt her marriage needed. Her therapist diagnosed her as having a recurrent major depressive episode, told her Hamilton score, and suggested that the episode was related to a worsening role dispute with her husband. Ms. A agreed to a 12-week course of IPT and was given the sick role.

Sessions focused on marital communication, but started with the therapist eliciting the patient’s feelings about her marriage and her husband. They discussed her own and her husband’s disappointment about not having children, and her feelings that her husband found her inadequate in the absence of children. She loved her husband, who also had many good qualities, but was also upset with his withdrawal and apparent blame of her. The therapist normalized Ms. A’s feelings, encouraged her to put them into words, and role played with her what she wanted to say, and in what tone of voice. They discussed contingencies: how she might approach him, and what she could do if he got angry.

Ms. A feared her husband’s rage, but she agreed with her therapist that it would be helpful to be able to communicate feelings and that their infertility was a major life event (which might alternatively have been characterized as a role transition). After some weeks of rehearsal, she risked confronting him. She noted that they had been going through a hard time, that their marriage had become strained, but that she really wanted to work with Mr. A to make it better. She also confessed her fears that he no longer loved her and was seeing someone else.

Mr. A was initially taken aback and defensive. Ms. A returned to the next therapy session discouraged. Ms. A and her therapist then reviewed the encounter and explored options for how she could broach the topic at a calmer time of the week than previously. They role played this interaction, with Ms. A testing different expressions of her feeling and different tones of voice. On the next try, to the patient’s relief, Mr. A opened up rather surprisingly, nearly crying in talking about their inability to have a child and convincingly denying any extramarital affairs—although he admitted having been tempted. Ms. A’s symptoms improved markedly in the aftermath of this breakthrough. The couple began to weigh adoption against the benefits of childlessness: the freedom to travel, live a wealthier lifestyle, and so forth. Mr. A began returning home from work earlier, and the couple planned a vacation. By the end of treatment, the marriage was stronger and the couple communicated better than ever previously. They were proceeding with plans for adoption.

Ms. A was euthymic, with a Hamilton Depression score of 4. In the termination phase, the IPT therapist emphasized Ms. A’s improvement was due to her own actions, to her finding more effective ways to communicate with her husband in resolving their role dispute. Although they were terminating acute treatment, the therapist pointed out that Ms. A had now had two episodes of major depression and was at significant risk for a third. Accordingly, they agreed to continuation treatment with monthly sessions of IPT.

Research Findings: IPT for Mood Disorders
IPT outcome research has been continual, precluding an exhaustive description of studies. What follows is a selection of key research trials of IPT for mood and other disorders. For some of these trials, IPT was adapted in a separate manual, but in all cases the general principles of the treatment remained the same. (See Table 88–4.)

| In the 1970s, IPT was first tested as an acute antidepressant treatment in a four-cell, 16-week randomized trial. This compared IPT, amitriptyline (AMI), their combination, and a nonscheduled control treatment for 81 outpatients with major depression (DiMascio et al. 1979, Weissman et al. 1979). AMI alleviated symptoms more quickly, but no significant difference appeared between IPT and AMI in symptom reduction at the end of treatment. Each active treatment reduced symptoms more efficaciously than the nonscheduled control, and combined AMI–IPT was more efficacious than either active monotherapy. Patients with psychotic depression fared poorly on IPT alone. At 1-year follow-up, many patients sustained improvement from the brief IPT intervention, and IPT patients had developed significantly better psychosocial functioning whether or not they received medication. This effect on social function was not found for AMI alone and had not been evident for IPT at the end of the 16-week trial (Weissman et al. 1981).

In the landmark, multisite National Institute of Mental Health Treatment of Depression Collaborative Research Program (NIMH TDCRP) (Elkin et al. 1989), investigators randomly assigned 250 outpatients with major depression to 16 weeks of IPT, CBT, or either imipramine (IMI) or placebo with clinical management. Most subjects completed at least 15 weeks or 12 treatment sessions. Patients with milder depression (defined as a 17-item HDRS score >20) improved equally in all four treatments. For more severely depressed patients (HDRS ≥20), IMI worked fastest and most consistently better than placebo. IPT and IMI were comparable on several outcome measures, including HDRS, and superior to placebo for more severely depressed patients. CBT was not superior to placebo among the more depressed patients.

Klein and Ross (1993) reanalyzed the TDCRP data using the Johnson–Neyman technique. They reported an ordering for treatment efficacy with “medication superior to psychotherapy, [and] the psychotherapies somewhat superior to placebo . . . particularly among the symptomatic and impaired patients” (Klein and Ross 1993, p 241), and found “CBT relatively inferior to IPT for patients with BDI scores greater than approximately 30, generally considered the boundary between moderate and severe depression” (p 247).

*Preliminary results encouraging.
The reanalysis does not contradict the earlier report of Elkin et al. (1989), but sharpens differences among treatments. Following up the TDCRP subjects 18 months later, Shea et al. (1992) found no significant difference in recovery among remitters (who had minimal or no symptoms after the end of treatment, sustained during follow-up) among the four treatments. Thirty percent of CBT, 26% of IPT, 19% of IMI, and 20% of placebo subjects who had acutely remitted remained in remission during that time span. Among acute remitters, relapse over the 18-month follow-up was 36% for CBT, 33% for IPT, 50% for IMI (medication having been stopped at 16 weeks), and 33% for placebo. The authors concluded that, for many patients, 16 weeks of specific treatments were insufficient to achieve full and lasting recovery.

**Maintenance Treatment**

IPT was first developed for and tested in an 8-month, six-cell trial (Klerman et al. 1974, Paykel et al. 1975). This study today would be considered a “continuation” treatment, as the concept of long-term maintenance antidepressant treatment has lengthened. Acutely depressed outpatient women ($N = 150$) who had responded with at least 50% symptom reduction rated by a clinical interviewer to a 4–6 week acute phase of AMI were randomly assigned to receive 8 months of weekly IPT alone, AMI alone, placebo alone, combined IPT–AMI, IPT–placebo, or no pill. Randomization to IPT or a low contact psychotherapy condition occurred at entry into the continuation phase, whereas randomization to medication, placebo, or no pill occurred at the end of the second month of continuation. Continuation pharmacotherapy prevented relapse and symptom exacerbation, whereas IPT improved social functioning (Weissman et al. 1974). The effects of IPT on social functioning did not appear for 6–8 months. Combined psychotherapy–pharmacotherapy had the best outcome.

Longer antidepressant maintenance trials of IPT have been conducted in Pittsburgh. Frank et al. (Frank et al. 1990, Frank et al. 1991) treated 128 outpatients with multiply and rapidly recurrent depression. Patients initially received combined high dose (>200 mg/day) IMI and weekly sessions of IPT. Responders remained on high dosage medication while IPT was tapered to a monthly frequency during a 4-month continuation phase. Patients who remained remitted were then randomly assigned to 3 years of either (1) ongoing high dose IMI plus clinical management, (2) high dose IMI plus monthly IPT, (3) monthly IPT alone, (4) monthly IPT plus placebo, or (5) placebo plus clinical management. High dose IMI proved the most efficacious treatment, protecting more than 80% of patients over 3 years. In contrast, most patients on placebo relapsed within the first few months. In maintenance IPT, therapists were permitted to switch interpersonal sex in order to deal with patients’ current life problems. Once a month IPT, while less efficacious than medication, was statistically and clinically superior to the placebo condition in this high risk patient population. Reynolds et al. (1999) essentially replicated these maintenance findings in a study comparing IPT and nortriptyline for geriatric patients with recurrent major depression.

Women of childbearing age are the modal patients with depression. The study finding of an 82-week survival time without recurrence on IPT would suffice to protect many women with recurrent depression through pregnancy and nursing without medication. Further study is required to determine the efficacy of IPT relative to newer medications (e.g., selective serotonin reuptake inhibitors), and the efficacy of dosages other than once-monthly maintenance IPT. A study of differing doses of maintenance IPT for depressed patients in Pittsburgh, not yet published, has not found differences in outcome based on frequency of sessions. Perhaps optimal dosing of maintenance IPT depends on individual patients’ needs.

**Geriatric Depressed Patients**

IPT was first used with geriatric depressed patients as augmentation to a 6-week pharmacotherapy trial in order to enhance compliance and to provide some treatment for the placebo control group (Rothblum et al. 1982, Sholomskas et al. 1983). The investigators reported that grief and role transition specific to life changes were the prime focus of treatment. They suggested modifications of IPT including more flexible duration of sessions, greater use of practical advice and support (e.g., arranging transportation, calling the physician), and recognizing that major role changes may be impractical and detrimental (e.g., divorce at age 75). The 6-week trial compared standard IPT to nortriptyline in 30 geriatric depressed patients. Results showed some advantages for IPT, largely because of higher attrition in the medication group due to nortriptyline side effects (Sloane et al. 1985).

Reynolds et al. (1999) conducted a 3-year maintenance study for geriatric patients with recurrent depression in Pittsburgh using IPT and nortriptyline in a design similar to the Frank et al. (1990) study. The IPT manual was modified to allow more flexible length of sessions, under the assumption that some elderly patients might not tolerate 50-minute sessions. The authors found older patients needed to address early-life relationships in their psychotherapy, a distinction from the typical “here and now” focus of IPT. Like Sholomskas et al. (1983), they felt that therapists needed to help patients solve practical problems and to acknowledge that some problems may not be amenable to resolutions, such as existential late life issues or lifelong psychopathology (Rothblum et al. 1982). Elderly depressed patients whose sleep quality normalized by early continuation phase had an 80% chance of remaining euthymic during the first year of maintenance treatment. The response rate was similar for patients who subsequently received either nortriptyline or IPT.

Reynolds et al. (1999) acutely treated 187 geriatric patients (60 years and older) with recurrent major depression using combined IPT and nortriptyline. One hundred seven remitted and then achieved recovery after continuation therapy. They were randomly assigned to one of four 3-year maintenance conditions: (1) medication clinic with nortriptyline alone, with steady-state nortriptyline plasma levels maintained in a therapeutic window of 80–120 ng/ml; (2) medication clinic with placebo; (3) monthly maintenance IPT with placebo; or (4) monthly IPT-M plus nortriptyline. Recurrence rates were 43% for nortriptyline alone, 90% for placebo, 64% for IPT with placebo, and 20% for combined treatment. Each monotherapy was statistically superior to placebo, whereas combined therapy showed superiority to IPT alone and a trend for superiority over medication alone.

Patients in their 70s were more likely to suffer recurrence and to do so more quickly than patients in their 60s.
This study corroborates the maintenance findings of Frank and colleagues, with the difference that combined treatment had advantages over pharmacotherapy alone for the geriatric population. In a follow-up study, Reynolds and colleagues again found that once-monthly maintenance IPT was not efficacious in preventing relapse of depressed patients 70 years or older who had responded to the combination of IPT and paroxetine (Reynolds et al. 2006).

It is easy to misinterpret the comparison of high dose tricyclic antidepressants to low dose IPT-M in both the Frank et al. and the Reynolds et al. (1999) studies. Had the tricyclics been lowered comparably to the psychotherapy dosage, recurrence in the medication groups might well have been greater. Yet this was unprecedented research. Under the circumstances, the choice of monthly dosing for IPT-M, while the lowest ever prescribed in a psychotherapy trial, was reasonable, and indeed showed some benefit.

**Depressed Adolescents (IPT-A)**

Mufson et al. (2004a) modified IPT to incorporate adolescent developmental issues. They conducted an open feasibility and follow-up trial, and then a controlled 12-week clinical trial comparing IPT-A and clinical monitoring in 48 clinic-referred adolescents, ages 12–18, who met DSM-III-R criteria for MDD. Patients were seen biweekly by blind independent evaluators to assess symptoms, social functioning, and social problem-solving skills. Thirty-two of the 48 patients completed the protocol (21 IPT-A, 11 control).

Patients receiving IPT-A reported significantly greater improvement in depressive symptoms and overall social functioning, including functioning with friends and problem-solving skills. In the intention-to-treat sample, 75% of IPT-A patients met the criterion for recovery (HDRS score ≤ 6), compared to 46% of control patients. These findings support the feasibility, patient acceptance, and efficacy of 12 weeks of IPT-A with acutely depressed adolescents in reducing depressive symptoms and improving social functioning and interpersonal problem-solving skills (Mufson et al. 1999). Mufson et al. (2004b) subsequently tested IPT-A in an effectiveness study in school-based clinics, where they found it markedly superior to treatment as usual. The same group is now studying IPT-A in a group format for depressed adolescents (Mufson et al. 2004c) and training therapists in IPT-A in larger health care systems.

Rosello, Bernal, and Rivera at the University of Puerto Rico randomly assigned adolescents, ages 13–18, who met DSM-III-R criteria for major depression, dysthymia, or both, to 12 weeks of IPT (n = 22), CBT (n = 25), or a waiting-list control condition (n = 24). The investigators found both IPT (effect size 0.73) and CBT (effect size 0.43) more efficacious than the control condition in reducing adolescents’ self-rated depressive symptoms. IPT increased self-esteem and social adaptation more effectively than CBT (Rosello and Bernal 1999).

**Depressed HIV-Positive Patients (IPT-HIV)**

Markowitz et al. (1992) modified IPT for depressed HIV patients (IPT-HIV), emphasizing common issues among this population including concerns about illness and death, grief and role transitions. In a pilot open trial, 21 of the 24 depressed patients responded with symptom reduction. A 16-week study randomized 101 subjects to IPT-HIV, CBT, supportive psychotherapy (SP), and IMI plus SP (Markowitz et al. 1998). Echoing the results of the more severely depressed subjects in the TDCRP study (Elkin et al. 1989), all treatments were associated with symptom reduction, but IPT and IMI-SP produced symptomatic and functional improvement significantly greater than CBT or SP. Many patients reported improvement in depressive physical symptoms that they had mistakenly attributed to HIV infection.

**Depressed Primary Care Patients**

Schulberg and colleagues compared IPT and nortriptyline for depressed ambulatory medical patients in a primary care setting. (Schulberg and Scott 1991, Schulberg et al. 1993). They did not modify the IPT manual, but integrated IPT into the routine of the primary care center; for example, nurses took vital signs before each session. If patients were medically hospitalized, IPT was continued in the hospital when possible.

Patients with current major depression (n = 276) were randomly assigned to IPT, nortriptyline, or primary care physicians’ usual care. They were seen weekly for 16 weeks and monthly thereafter for 4 months in IPT (Schulberg et al. 1996). Depressive symptom severity declined more rapidly with either nortriptyline or IPT than in usual care. Approximately 70% of treatment completers receiving nortriptyline or IPT, but only 20% in usual care, had recovered after 8 months. Brown et al. (1996) found that subjects with a lifetime history of comorbid panic disorder had a poorer response across treatments, compared to those with major depression alone. Frank et al. (2000a) found a similar effect for comorbid panic disorder on depressive outcome.

These studies in depressed medically ill patients suggest that the life event of medical illness may provide a useful focus as a role transition in IPT treatment (cf. Koszycoki et al. 2004). On the other hand, a large study recently showed that IPT conferred no advantage to depressed patients with coronary artery disease (Lesperance et al. 2007).

**Conjoint IPT for Depressed Patients with Marital Disputes (IPT-CM)**

Marital conflict can precipitate or complicate depressive episodes (Rounsaville et al. 1979). Some clinicians believe that individual psychotherapy for patients in marital disputes may lead to premature rupture of marriages (Gurman and Kniskern 1978). Researchers at Yale University developed a manual for conjoint therapy of depressed patients with marital disputes (IPT-CM) (Klerman and Weissman 1993). IPT-CM includes the spouse in all sessions and focuses on the current marital dispute. Eighteen patients with major depression linked to the onset or exacerbation of marital disputes were randomly assigned to 16 weeks of either individual IPT or IPT-CM. Patients in both treatments showed similar reductions in depressive symptoms, but patients receiving IPT-CM reported significantly better marital adjustment, marital affection, and sexual relations (Foley et al. 1989). These pilot findings require replication with a larger sample and other control groups.

**Peripartum Depression**

Pregnancy and its aftermath are times of heightened depressive risk when women may wish to avoid antidepressant medication. Pregnancy and the postpartum also provide natural
role transitions as an IPT focus. Spinelli used IPT to treat women with antepartum depression. Exploring this role transition addresses the depressed pregnant woman’s self-evaluation as a parent, physiologic changes of pregnancy, and altered relationships with the spouse or significant other and with other children. Spinelli added “complicated pregnancy” as a fifth interpersonal problem area. Timing and duration of sessions are adjusted in response to bedrest, delivery, obstetrical complications, and child care. Postpartum mothers may bring children to sessions. As with depressed HIV-positive patients, telephone sessions and hospital visits are sometimes necessary (Spinelli 1997). A controlled clinical trial comparing IPT to a didactic parent education group in depressed pregnant women over 16 weeks of acute treatment showed advantages for IPT (Spinelli and Endicott 2003).

O’Hara et al. (2000) randomly assigned 120 women with postpartum depression to IPT or a waiting-list control in a 12-week trial with an 18-month follow-up. The investigators assessed the mothers’ symptoms and their interactions with their infants (Stuart and O’Hara 1995). In the IPT group, 38% met HDRS and 44% met BDI remission criteria, compared to 14% on each measure for the waiting-list group. Sixty percent of IPT patients, versus 16% of controls, reported more than a 50% reduction on the BDI. Women receiving IPT also showed significant improvement in social adjustment relative to controls.

Klier et al. (2001) treated 17 women with postpartum depression in 9 weekly 90-minute group sessions plus an hour-long individual termination session. Scores on the 21-item Ham-D fell from 19.7 to 8.0, suggesting the efficacy of this approach. In another trial. Zlotnick et al. (2001) treated 37 women at risk for postpartum depression with either four 60-minute sessions of an IPT-based group or usual treatment. None of 17 in the interpersonal group developed depression 3 months postpartum, whereas 6 of 18 in the control condition did. This preventive application of what sounds like a group form of interpersonal counseling (Klerman et al. 1987) needs replication, but is exciting.

**Dysthymic Disorder (IPT-D)**

A modification of IPT for dysthymic disorder encourages patients to reconceptualize what they have considered their lifelong character flaws as ego-dystonic, chronic mood-dependent symptoms: as chronic but treatable “state” rather than immutable “trait.” Therapy itself was defined as an “iatrogenic role transition,” from believing oneself flawed in personality to recognizing and treating the mood disorder. Markowitz (1994, 1998) openly treated 17 pilot subjects with 16 sessions of IPT-D; none worsened, and 11 remitted. Medication benefits roughly half of dysthymic patients (Kocsis et al. 1988, Thase et al. 1996), but nonresponders may need psychotherapy, and even medication responders may benefit from combined treatment (Markowitz 1994).

Based on these pilot results, a randomized trial at Cornell Medical College compared 16 weeks of IPT-D alone, SP, sertraline plus clinical management, as well as a combined IPT/sertraline. All groups improved, but IPT showed no greater acute benefits than SP, and pharmacotherapy appeared more efficacious than either psychotherapy (Markowitz et al. 2005).

Browne et al. (2002) at McMaster University in Hamilton, Canada, treated more than 700 dysthymic patients in the community with either 12 sessions of standard IPT over 4 months, sertraline for 2 years, or their combination. Patients were followed for 2 years. Using the criterion of a 40% reduction in score of the Montgomery-Asberg Depression Rating Scale (MADRS) at 1-year follow-up, 51% of IPT-alone subjects improved, significantly fewer than the 63% taking sertraline and 62% in combined treatment. On follow-up, however, IPT was associated with significant economic savings in use of health care and social services. Thus combined treatment was as efficacious as, but less expensive than, sertraline alone.

Feijó de Mello et al. (2001) randomly assigned 35 dysthymic outpatients to receive moclobemide with or without 16 weekly sessions of IPT. Both groups improved, but there was a nonsignificant trend for greater improvement on the Ham-D and MADRS in the combined treatment group. Similarly, Hellerstein et al. (2001) found that a group combining interpersonal and cognitive elements improved outcome over fluoxetine alone among dysthymic patients responding to fluoxetine.

Chronic depression is by and large more difficult to treat than acute depression, in part due to the ingrained despair that attends its very chronicity. IPT has not fared particularly well as a monotherapy for chronically depressed patients, but it may yet have benefit as an adjunct to medication, much as it may for bipolar disorder.

**Bipolar Disorder**

Frank and colleagues in Pittsburgh assessed the benefits for 175 bipolar patients of adjunctive IPT modified by social Zeitgeber theory—behavioral scheduling of daily and sleep patterns (Ehlers et al. 1988, Malkoff-Schwartz et al. 2000)—as maintenance treatment of medication-treated bipolar patients, comparing IPSRT (interpersonal social rhythms therapy) to medication clinic (Frank et al. 2005). The behavioral component helps to protect sleep patterns and limit the disruptions that may provoke mania; the IPT approach to depression remains largely the same.

Acutely ill bipolar patients were treated with medication and randomly assigned to IPSRT or clinical management (CM). After achieving 4 weeks of stabilization, they were again randomized to either IPSRT or CM for 3 years of maintenance treatment while continuing pharmacotherapy. Overall results of this complicated trial indicated that although there was no difference in time to initial stabilization of symptoms, IPSRT with medication was superior to the comparison condition in delaying recurrence of depressive and manic episodes (Frank et al. 2005).

**Subsyndromally Depressed Hospitalized Elderly**

Patients Mossey et al. (1996) noted that even depressive symptoms not reaching the threshold for major depression impeded recovery of hospitalized elderly patients. They conducted a 10-session trial of a simplified modification of IPT called interpersonal counseling (IPC; Klerman et al. 1987), provided by nonpsychiatric nurses, for elderly hospitalized medical patients with minor depressive symptoms. Patients were seen for hour-long sessions on a flexible schedule to accommodate the patient’s medical status. Seventy-six hospitalized patients over age 60, who had subsyndromal depressive symptoms on two consecutive assessments, were
neither IPT nor CBT showed efficacy as an outpatient treatment. Fairburn et al. (1993) adapted IPT for bulimic patients, eliminating the use of the sick role and of role playing in order to contrast distinct therapeutic strategies in comparing IPT and CBT. Initial trials showed that although CBT worked faster to relieve bulimic symptoms, IPT had longer term benefits comparable to CBT and superior to a behavioral control condition (Fairburn et al. 1993, 1995). A subsequent multisite trial found CBT superior to IPT (Agras et al. 2000). Nonetheless, IPT is one of the better tested treatments for bulimia, and at least a second line treatment after CBT.

IPT for Nonmood Disorders

The efficacy of IPT as an antidepressant treatment has led to its adaptation as a treatment for other psychiatric disorders. Life events are ubiquitous, but when is it useful to focus treatment on them? Research is beginning to answer such questions.

Bulimia

Fairburn et al. (1993) altered IPT for bulimic patients, eliminating the use of the sick role and of role playing in order to contrast distinct therapeutic strategies in comparing IPT and CBT. Initial trials showed that although CBT worked faster to relieve bulimic symptoms, IPT had longer term benefits comparable to CBT and superior to a behavioral control condition (Fairburn et al. 1993, 1995). A subsequent multisite trial found CBT superior to IPT (Agras et al. 2000). Nonetheless, IPT is one of the better tested treatments for bulimia, and at least a second line treatment after CBT.

Willetly et al. (1993, 2000, 2002) modified IPT in a 16-week, 90-minute session group format. The initial IPT phase, in which the therapist identifies problem areas, presents IPT concepts, and offers a treatment contract, is conducted individually; confusion was avoided among IPT problem areas by giving almost all subjects a focus on “interpersonal deficits.” They compared IPT-G to group CBT and a waiting-list control for 56 women with nonpurging bulimia. At termination, binge eating decreased in the IPT-G and CBT groups, but not in the control condition. Results persisted at 1-year follow-up. A randomized clinical trial of 162 women, comparing group IPT and CBT for 20 sessions over 20 weeks, yielded similar results (Willetly et al. 2002).

A research group in Christchurch, New Zealand, studied the application of IPT to anorexia nervosa. In their trial, neither IPT nor CBT showed efficacy as an outpatient treatment, a finding unfortunately consonant with anorexia outcome literature generally (McIntosh et al. 2005).

Social Phobia

IPT has not yet been tested in controlled studies for anxiety disorders. Two research groups have independently modified IPT for social phobia. Lipsitz et al. (1999) at Columbia University treated 9 IPT pilot cases and found promising results for social phobia. They found that such standard IPT ingredients as the medical model, provision of the sick role, and the supportive therapeutic stance, appear to benefit most patients. A small controlled trial has not yet been published. Weissman and Jacobson at Columbia have adapted IPT in a 10-session group format for sixty patients with social phobia in unstructured interpersonal situations: at parties, in intimate discussions with significant others, but not in defined work situations. In Norway, a research group has adapted Lipsitz’ model to compare group and individual IPT with CBT in a residential setting for patients with treatment refractory social phobia.

Panic Disorder

Arzt and colleagues in Maastricht, the Netherlands, are studying IPT as a treatment for panic disorder. Lipsitz et al. (2006) report promise for IPT in a small open trial.

Posttraumatic Stress Disorder (PTSD)

PTSD is an anxiety disorder defined by a life event, suggesting the utility of IPT in its treatment. Krupnick and colleagues are assessing a group form of IPT for multiply victimized women in public sector gynecology clinics in Virginia. Markowitz and colleagues at Cornell University modified IPT as an alternative to exposure-based psychotherapies for PTSD and found excellent outcomes in a small pilot trial (Bleiberg and Markowitz 2005). A controlled comparison is now planned.

Substance Abuse

IPT has failed to demonstrate efficacy in three clinical trials for patients with substance dependence. Rounsaville et al. (1983) studied 72 methadone-maintained opiate users and found that adding adjunctive IPT to standard substance abuse care at Yale (which already included a psychotherapy component) had no additional benefit in reducing psychopathology. Both treatment groups improved. The same research group found that 12 weeks of IPT were ineffective and marginally worse than a behavioral control for 42 subjects with cocaine abuse attempting to achieve abstinence (Carroll et al. 1991). Most recently, Carroll et al. (2004) treated 121 cocaine-dependent subjects in a 2 × 2 cell, 12-week trial, with either IPT or CBT and disulfiram 250 mg or placebo. CBT and disulfiram were superior to IPT and to placebo. These negative studies suggest limits to the range of utility of IPT, but do not necessarily preclude its use for all substance abuse. IPT might be useful, for example, as a treatment for newly abstinent alcohol-dependent patients, who face psychosocial stressors that have been shown to precipitate relapse.

Other Applications

Research groups are testing the applicability of IPT to body dysmorphic disorder, chronic somatization in primary care patients, depressed patients post myocardial infarction, depressed cancer patients, borderline personality disorder (Markowitz et al. 2006b), insomnia, and other disorders (Weissman et al. 2000). The IPT focus on life events suggests its potential applicability to patients with medical illness. Swartz et al. (2004) produced preliminary findings suggesting that IPT can be effective in a briefer, eight-session form.

Interpersonal Counseling (IPC)

Many patients presenting to primary care practices report psychiatric symptoms, but do not meet threshold criteria for a psychiatric disorder. Nonetheless, their symptoms can
be debilitating and may result in high wasted utilization of medical resources (Wells et al. 1989). IPC, based on IPT, was designed to treat distressed primary care patients who do not meet full syndromal criteria for psychiatric disorders. IPC is administered for a maximum of six sessions by health care professionals who lack formal psychiatric training, usually nurse practitioners. The first session can last up to 30 minutes; subsequent sessions are briefer.

IPC therapists assess the patient’s current functioning, recent life events, occupational and familial stressors, and changes in interpersonal relationships. They assume that such events provide the context in which emotional and bodily symptoms occur. Klerman et al. (1987) studied 128 patients in a primary care clinic who scored 6 or higher on the Goldberg General Health Questionnaire (GHQ), randomizing them to IPC or to UC without psychological treatment (Klerman et al. 1987). Over an average of 3 months, often receiving only one or two IPC sessions, IPC subjects showed significantly greater symptom relief on the GHQ than controls, especially mood improvement. IPC subjects were more likely to subsequently make use of mental health services, suggesting a new awareness of the psychological aspect of their symptoms.

A dramatic study demonstrating the transplantability of IPT to a very different culture tested a group variant of IPC in randomly assigned villages in a poverty- and AIDS-stricken region of Uganda where depression rates are high. IPT was selected as an intervention because antidepressant medication was unaffordable and other psychotherapies seemed incompatible with the local outlook. Researchers adjusted for cultural differences but applied the usual IPT paradigm. Local college graduates without mental health experience provided treatment. The group IPC intervention was impressively more effective than treatment as usual (Bolton et al. 2003), and gains persisted at 6-month follow-up (Bass et al. 2006).

**IPT by Telephone**

Because many patients avoid or have difficulty reaching an office for face-to-face treatment, IPC is being tested as a telephone treatment. Weissman and Miller at Columbia University conducted a successful pilot feasibility trial comparing IPT by telephone to no treatment in 30 patients with recurrent major depression who had not received regular treatment (Miller and Weissman 2002). Neugbauer et al. (2006) found telephone IPC a helpful intervention for women with minor depression post miscarriage.

**IPT Patient Guide**

Weissman (1995) developed an IPT patient guide with worksheets for depressed readers who want information about or are receiving IPT. Worksheets can be used to facilitate sessions or to monitor problem areas after treatment. The utility of the patient book in enhancing treatment has not been studied.

**Summary**

IPT has demonstrated efficacy as an acute and maintenance monotherapy and as a component of combined treatment for major depressive disorder. It also appears to have utility for other mood and nonmood syndromes, although the evidence for these is sparser. It has not shown benefit for substance use disorders or as a monotherapy for dysthymic disorder. Since monotherapy with either IPT or pharmacotherapy is likely to suffice for most patients with major depressive disorder, combined treatment is probably best reserved for severely or chronically ill patients (Rush and Thase 1999). How best to combine time-limited psychotherapy with pharmacotherapy—for which patients, in what sequence, etc.—is an exciting area for future research.

When two or more treatments have demonstrated efficacy for a diagnosis such as major depressive disorder, when is one treatment more likely to have a better outcome than another? Comparative trials are beginning to reveal moderating factors or predictors of treatment outcome. Studies such as the NIMH Treatment of Depression Collaborative Research Program, which compared IPT and CBT, have suggested factors that might predict better outcome with either IPT or CBT. (See Table 88–5.)

Sotsky et al. (1991) found that depressed patients with a low baseline level of social dysfunction responded well to IPT, whereas those with severe social deficits (probably...
equivalent to the “interpersonal deficits” problem area) responded less well. Patients with greater symptoms on severity and difficulty in concentrating responded poorly to CBT. Initial severity of major depression and of impaired functioning predicted superior response to IPT and to imipramine. Imipramine also worked most efficaciously for patients with difficulty functioning at work, likely reflecting its faster onset of action. Patients with atypical depression responded better to either IPT or CBT than to imipramine or placebo (Shea et al. 1999).

Barber and Muenz (1996), looking only at TDCRP completers, found IPT more efficacious than CBT for patients with obsessive personality disorder, whereas CBT fared better for avoidant personality disorder. Biological factors such as abnormal sleep profiles on EEG predicted significantly poorer response to IPT than for patients with normal sleep parameters (Thase et al. 1997). Frank et al. (1991) found that psychotherapist adherence to a focused IPT approach may enhance outcome. The replication and further elaboration of these predictive factors deserve ongoing study.

Training

Until recently, IPT therapists were few, and practiced almost exclusively in research studies. Publications supporting its efficacy have led to clinical demand for this empirically supported treatment. IPT training is now increasingly included in professional workshops and conferences, with training courses conducted at university centers in Canada, the United Kingdom, continental Europe, Asia, New Zealand, and Australia. IPT is taught in a small but growing minority of psychiatric residency training programs in the United States (Markowitz 1995, Lichtmacher et al. 2006) as well as some family practice and primary care training programs.

Although the principles and practice of IPT are relatively straightforward, any psychotherapy requires innate therapeutic ability, comfort with the so-called “common factors” of psychotherapy (Frank 1971): tolerating and exploring affect, helping the patient to feel understood, engendering hope, etc. IPT training requires more than reading the manual (Weissman et al. 1982, Rounsaville et al. 1988): psychotherapy is learned by doing. Most IPT training programs are designed to help experienced therapists refocus their treatment by learning new techniques, not to teach novices psychotherapy. Candidates should have a graduate clinical degree (M.D., Ph.D., M.S.W., R.N.), several years of experience conducting psychotherapy, and clinical familiarity with the diagnosis of patients they plan to treat.

The IPT training in the TDCRP (Elkin et al. 1989) became the model for subsequent research studies. It included a brief didactic program, reading the manual, and a practicum in which the therapist treated 2–3 patients under close supervision monitored by videotapes of the sessions (Chevron and Rounsaville 1983). Rounsaville et al. (1986) found that psychotherapists who performed well on an initial supervised IPT case often required no further intensive supervision, and that experienced therapists committed to the approach required less supervision than others (Rounsaville et al. 1988). Some clinicians have taught themselves IPT using as guides the IPT manual (Klerman et al. 1984, Weissman et al. 2000) and peer supervision. For research certification, we continue to recommend at least two or three successfully treated cases with hour for hour supervision of taped sessions (Markowitz 2001).

A loose IPT umbrella organization, the International Society for Interpersonal Psychotherapy (IS IPT; www.interpersonalpsychotherapy.org) has now held biennial international scientific meetings. Although many clinicians would like a formal certificate or diploma in IPT, there is no gold standard of IPT proficiency and no accrediting board. When IPT practice was limited to research settings, this posed no problem: one research group taught another, in the manner described above. As IPT spreads in clinical practice, questions of competence and accreditation gain greater urgency. Training programs in IPT are still not widely available, as a Surgeon General’s report noted (Satcher 1999). Many psychiatry residency, psychology, and social work training programs still provide limited exposure to evidence-based treatments like IPT (Weissman et al. 2006).

The educational process for IPT in clinical practice requires further study. We do not know what levels of education and experience are required to learn IPT, nor how much supervision an already experienced psychotherapist is likely to require.

The Future

The history of IPT has been a succession of outcome trials. These studies have helped to define diagnostic indications for this treatment. Because psychotherapy is underfunded relative to pharmacotherapy, we know far less about the dosage and indications of IPT than about antidepressant medication. Future outcome trials may continue to define the territory of IPT’s utility. These should include both tests for different diagnoses, such as the anxiety disorders, testing of dosage—optimal frequency and duration of IPT sessions—and also studies of the sequencing of IPT with other treatments. For example, when, and for whom, is IPT best combined with pharmacotherapy? Is it best to start with pharmacotherapy and then add IPT? If so, at what interval, and with what frequency? When should IPT be used as augmentation for pharmacotherapy, and vice versa? Other research may help to determine the cost-effectiveness and potential cost-offset of IPT as a treatment that improves both symptoms and social functioning.

IPT is also anomalous among psychotherapies in its nearly pure focus to date on outcome studies. Until recent decades, most psychotherapy research was process research, an analysis of what occurred between patient and therapist in sessions. The late Gerald L. Klerman emphasized the primacy of outcome research, emphasizing that if the therapy had no actual clinical benefit, its mechanism would hold little interest. Now that it is clear that IPT helps many patients, process research seems warranted to try to identify its active, mediating factors. Little is known about the specific value of many IPT interventions. It is even unclear, for example, whether focusing on a role transition rather than a role dispute makes a difference for patients, or whether particular sorts of life events are helpful or unhelpful foci. It does appear that solving an interpersonal problem area correlates with treatment outcome, as IPT theory would predict (Markowitz et al. 2006a). Patient and therapist characteristics may also potentially influence treatment outcome.

Clinical training in IPT is growing. How it spreads will be a function of training programs. Training will eventually
require formalized accreditation, both to ensure clinical competence and to satisfy managed care organizations. Research is needed on how best to teach and disseminate IPT.

In summary, IPT is a time-limited, forward-looking, pragmatically focused psychotherapy that defines psychiatric disorders as treatable medical illnesses and links them to the patient’s current social situation. This strategy has proved efficacious for patients with major depression and bulimia, and shows promise for other mood and nonmood disorders.

Having evolved from psychoanalytic roots, brief therapy today has a number of distinct models with the common aim of accelerating change through the active, focused interventions of therapists and increased patient involvement in treatment. Brief therapies range from single-session treatments and very brief strategic interventions of several sessions to short-term psychodynamic modalities that frequently exceed 20 sessions. Many schools have developed manuals, making it easier to practice these techniques with fidelity and to conduct research. In fact, most research in psychotherapy is on brief therapy. This rich body of research clearly supports the efficacy of brief therapy in a broad range of patients and is helpful in delineating patients and presenting problems likely to benefit from these approaches.

The development of brief therapy models, manuals, and research evidence, combined with financial constraints and the fact that many patients get relief very quickly have led to brief therapy becoming the norm for the majority of patients.

Cognitive and behavioral therapies are the best studied and sometimes considered synonymous with both brief and evidence-based therapy. However, brief psychodynamic, interpersonal and other therapies are also evidence-based and shown to be effective. This chapter will broadly address brief therapy with an emphasis on brief psychodynamic therapy. Cognitive-behavioral and interpersonal therapies are covered in separate chapters.

A Short History Of Brief Therapy

Many early major figures in psychoanalysis contributed to the development of brief therapy. Freud himself described three cases in which psychoanalytic treatments lasted nine weeks (Lucie R), seven weeks (Emmy Von N) and one week (Katherine) (Breuer and Freud 1955). Brevity and a circumscribed focus are evident in his cure of the impotence of Gustave Mahler in a single, four-hour session (Jones 1957).

In 1920, Ferenczi (1920) first attempted to increase therapist activity in order to decrease the length of psychoanalytic therapy and promoted “active therapy.” This key ingredient remains a hallmark of modern brief therapy.

Otto Rank joined Ferenczi (Ferenczi and Rank 1925) in supporting a deliberate change toward brief therapy. He was first to use a fixed time frame: nine months to work on the “trauma of birth” (1924). He replaced the centrality of oedipal problems with the primacy of separation. Rank also suggested that short treatments required “willing” patients.

Alexander and French (1946) were the first to systematically research methods to abbreviate psychoanalysis. They argued that change was not primarily a function of insight, but of experience. Therefore, the therapist’s role was to foster “corrective emotional experiences” in which patients are re-exposed to past emotional situations in therapy sessions while the therapist behaves (either naturally or purposefully) in a more accepting, supportive and constructive manner than past significant figures did. For instance, if the patient had grown up in the presence of an unloving, angry father, the therapist would purposely attempt to be the opposite. The therapists’ role changed from “blank screens” to active treatment agents who could utilize their relationships with patients to catalyze needed developmental experiences.

French (1970) contributed another staple of brief therapy—the narrowed focus. He used the term “focal conflict” to describe the instance wherein a patient’s wish or impulse comes into conflict with their values and expectations, forcing a defensive compromise. Michael Balint, who founded the British School of brief dynamic psychotherapy at the Tavistock Clinic, further refined this concept into “focal psychotherapy” (Balint et al. 1972), which could be brief by design because it had limited aims and was focused on a narrow sector of the personality. Another important tenet was the direction to the patient to try out in the real world the knowledge and skills gained from treatment and even take periodic breaks from therapy in order to consolidate and integrate gains.

David Malan, Balint’s student, brought the British School into prominence by organizing the clinical and research base of focal therapy. Malan made a number of major contributions to the technical aspects of brief therapy. His treatment was truly time-limited and he fixed the termination date (irrespective of the number of sessions, which averaged around eighteen) at the initial meeting. He was the first to detail patient characteristics that made them suitable for brief therapy: absence of severe psychopathology, psychological mindedness, and “some circumscribed aspect...
of pathology that can be made into a focus, and hence . . . a possible therapeutic plan.” (Malan 1976, p 254). His technique was to maintain a narrow, clear focus and to offer transference interpretations of two “triangles of insight” (see Figure 89–1). In the “triangle of conflict,” an impulse or wish comes into focal conflict with a person’s moral prohibitions or threat of social sanctions, leading to a defensive compromise to reduce anxiety. The therapist was to interpret the defense first, but it was important to uncover the anxiety and underlying impulse. The “triangle of person” consists of recurring maladaptive relationships in the transference, in the present but outside the therapeutic relationship, and in the past with parental or caretaking figures. Interpretations are made to show that the same maladaptive pattern exists in each of the points of this triangle. Repeated transference interpretations linking the impulse from relationships with parental figures in the past and with the therapist currently is hypothesized to be the most beneficial.

Sifneos (1972) also found that patient selection was crucial to the success of his “short-term anxiety-provoking psychotherapy.” Patients did best who were intelligent, with good interpersonal skills, a history of at least one meaningful relationship, eagerness to change and presenting with a focused problem. In therapy, the task is to build rapport, construct a psychodynamic formulation of the “core neurotic problem,” and engage the patient in a shared focus for treatment. The therapist next addresses the patient’s positive transference and the wish to be taken care of in order to prevent regression and urges the patient to take responsibility for working in treatment. The past is explored but resistance is quickly addressed in the transference whenever it arises. Anxiety-provoking questions often also provoke anger and Sifneos models effective problem solving as a therapist-teacher working with a patient-student. When the therapist ascertains that symptomatic and interpersonal improvements have occurred in the area of focus and has generalized beyond the focus, it is time to begin the process of termination and a final date is set. Resistance to termination is addressed briefly and as a matter of fact. The emphasis is on treatment successes and growth. Therapy ends soon thereafter.

Luborsky (1984) built on the work of Sifneos and Malan to create supportive-expressive (SE) psychotherapy, with its characteristic core conflictual relationship theme (CCRT) that consists of three components: a wish, response from others, and a response of the self. SE has been used in some landmark studies of psychotherapy.

Mann’s Time Limited Psychotherapy integrates the four psychologies of drive, ego, object, and self. It is based on the “recurring life crisis of separation–individuation” (p 11), which is addressed by “the exact prescription of time” (Mann 1973, p 53). Therapy lasts 12 sessions, and the final session is scheduled during the first. It was critical to accurately ascertain the “central theme.” Mann’s four central themes relate to the patient’s ability to tolerate and manage object loss: independence versus dependence, activity versus passivity, adequate self-esteem versus diminished or loss of self-esteem, and unresolved or delayed grief.

Horowitz (1976) and Horowitz et al. (1984) developed specific dynamic techniques for treating trauma and stress response syndromes. He focused on current stressors but also found it necessary to address personality characteristics and underlying conflicts.

Habib Dananlo (1980) markedly broadened the selection criteria to include severe, long-standing neurotic and character pathology that is generally excluded by all other brief therapists. He emphasizes the importance of psychological resilience and gauges suitability for treatment in a one-to-several-hour-long “trial therapy” during which he works on “unlocking the unconscious”. He makes use of psychoanalytic “triangles of insight” but, unlike other theorists, can work with more than one focal conflict, especially when treating severely ill patients. Reminiscent of Wilhelm Reich’s classic work on character analysis (Reich 1933), Dananlo has a very active, direct style that insistently confronts the patient’s defenses and quickly clarifies and challenges resistance but maintains a therapeutic alliance by carefully allying with patients against their pathology, which is made ego-dystonic.

The Behaviorists. Skinner (1974) and Wolpe (1958) established the behavioral therapies in the 1950s. In behavior therapy, patients mastered new coping skills and altered their learned behavioral patterns. Therapy was highly circumscribed, emphasizing directive teaching and structured homework assignments between sessions. By the 1970s, behavior therapy had become part of the therapeutic mainstream (Skinner 1974) and has a wealth of research to support its efficacy in obsessive compulsive disorder, trauma, phobias and panic disorder (Foa and Kozak 1986, Kozak and Foa 1997, Barlow 2002). Also in the 1950s, Albert Ellis applied the learning paradigm to cognition and enunciated rational-emotive therapy, which blended the psychodynamic interest in the patient’s inner life with hands-on behavioral methods (Ellis and Harper 1961).
Cognitive therapists. Since the 1960s, Aaron Beck (1976) and others have applied cognitive therapy to a remarkably wide range of conditions, including depression, personality disorders and even schizophrenia (Beck et al. 1990, Beck and Rector 2000). In cognitive therapy patients unlearn dysfunctional thought patterns and acquire new, constructive ones. The combination of a tight treatment focus and structured patient involvement between sessions ensures that cognitive therapy, like its behavioral sibling, possesses core ingredients of brevity.

Cognitive-behavioral analysis system of psychotherapy (CBASP) combines cognitive, behavioral and interpersonal therapies. In one study, CBASP combined with nefazodone produced the highest response rate for chronic depression reported with any modality, 85% versus 55% for nefazodone alone and 52% for CBASP alone (Keller et al. 2000).

Strategic therapies. Another mainstream of brief therapy emerged with the writings of Milton Erickson and Jay Haley (Erickson and Haley 1967). Erickson viewed the presenting concerns of patients as failed efforts to solve normal life problems. The role of the therapist is neither as significant other nor cognitive-behavioral teacher, but as a problem solver who interrupts and redirects repeated self-reinforcing failures, often done in just a few sessions through the prescription of directed tasks. With the publication of Watzlawick et al.’s (1974) classic work on change processes, the strategic approach became a therapeutic staple, particularly in the work of family therapists.

The widespread adoption of so many schools of brief therapy raised legitimate concerns regarding the comparative efficacy of these different methods as well as possible limitations of such treatments, especially for severe and persistent emotional disorders and conditions with high relapse rates (Reed and Eisman 2006). Despite these concerns, and bolstered by positive findings, today brief therapies have become the practice rule rather than the exception.

It should be noted that there is a growing body of empirical evidence attesting to the cost-effectiveness of psychotherapy (Creed et al. 2003, Gabbard et al. 1997, Guthrie et al. 1999, Heuzenroeder et al. 2004). Though additional studies comparing psychotherapy to medication treatment cost effectiveness would be welcome (Barrett et al. 2005), a number of comparisons are indicative of why psychotherapy may be more cost-effective. For example, comparative trials of psychotherapy and medication for depression have shown that the beneficial effects of psychotherapy treatments are enduring while those for drug treatments do not continue once the treatments are stopped (Hollon et al. 1992, 2002). Lasting effects for psychotherapy are shown by the significant decrease in relapse rates following treatment (e.g., DeMaat et al. 2006, DeRubeis et al. 2005, Evans et al. 1992, Hollon 2003, Hollon et al. 2005, Shea et al. 1992). Research indicates that psychotherapy reduces vulnerability to depression once treatment terminates and that this may result from patients becoming more resilient in their ability to handle future stressful situations (Hawley et al. 2007). Therefore, brief therapies are not only clinically effective but also cost-effective.

Psychodynamic Therapy Issues, Outcomes and Comparisons

Evaluating how effective a particular brand of psychotherapy is has become an important task in recent decades. Relatively newer brands such as cognitive-behavioral therapy (CBT) and interpersonal therapy (IPT) have gained widespread acclaim by empirically demonstrating the value of these approaches in a variety of conditions, especially for mood and anxiety disorders (Beck 1995, 2005, Weissman et al. 2000, Stuart and Robertson 2003). Indeed, it has become fashionable to designate treatments as “empirically validated” or “evidence-based” when conventional scientific treatment trials demonstrate their worth. Many volumes and papers (e.g., Chambless 1998, Dewan et al. 2004, Prochaska and Norcross 2007, Smith et al. 1980, Wampold 2001) have documented that treatment conducted from a variety of theoretical schemes produce benefits. In this volume, specific chapters devoted to CBT (Chapter 91) and IPT (Chapter 88) speak to their effectiveness. Therefore, this chapter will focus on the usefulness of brief psychodynamic therapies, a focus that is timely because in the future “there will be no income without outcome” (Greenberg 2004b, p. 145).

After a painstaking review, Fisher and Greenberg (1985, 1996) concluded that therapies labeled “psychoanalysis” did not produce results superior to those from treatments that were often briefer and given other labels. Similar conclusions were reached by others (Bachrach et al. 1991, Luborsky and Spence 1978).

Could it be that orthodox psychoanalysis, with its emphasis on lengthy treatments, is simply an inefficient method of the briefer psychodynamic psychotherapies, which reach comparable levels of improvement in a shorter time? (Fisher and Greenberg 1996). This provocative idea is consistent with meta-analyses that have failed to establish a simple, direct relationship between time in therapy and outcome (e.g., Miller and Berman 1983, Robinson et al. 1990, Shapiro and Shapiro 1982, Smith et al. 1980).

Efficacy of Brief Psychodynamic Psychotherapy: The Evidence

One problem in assessing how well brief psychodynamic therapy does is that there is no one form of this treatment that has been used in all or even most of the studies. There are several models of brief psychodynamic psychotherapy (Messer and Warren 1995). Prominent proponents of brief dynamic approaches include Davanloo (1978), Luborsky (1984, Luborsky and Crits-Cristoph 1990), Malan (1976), Mann (1973, Mann and Goldman 1982), Sifneos (1972, 1992), Levenson (1995), and Strupp and Binder (1984). Lack of treatment uniformity in the brief therapies is similar to the variability in analyst approach noted in studying long-term psychoanalysis (Fisher and Greenberg 1985, 1996). Nonetheless there are certain therapist interventions that the briefer forms of psychodynamic therapies have in common (Table 89–1).

In addition to the heightened level of therapist activities (Table 89–1), the research literature also reveals seven features, themes, or techniques that characterize brief psychodynamic approaches (Blagys and Hilsenroth 2000). These include: a focus on patients’ expression of emotions; exploration of patient resistance or avoiding discussion of
Meta-analyses of Brief Psychodynamic Psychotherapy

Therapist Interventions in Brief Psychodynamic Psychotherapy

- Designation of time limits (Usually 12 to 40 sessions)
- Attempts to create a prompt, sturdy, working alliance and positive transference
- Identification of core interpersonal problems within the initial sessions
- Increased therapist direction and activity
- More emphasis on predetermined goals
- More rapid use of general and transference interpretations

Though brief psychodynamic therapy approaches have risen to prominence over about the past 40 years, attempts at empirical validation with a wide range of patients in randomized, controlled trials have been most notable for the past 20 years. About 50 studies in the English language have appeared during that period of time (Abbass et al. 2006).

The growth in research studies has led to several attempts to analyze and summarize the literature using meta-analysis, a statistical technique that permits the combining of results from many studies to reach an overall conclusion about treatment outcome. Table 89–2 presents a listing of the five meta-analyses of brief psychodynamic psychotherapy conducted with adult outpatients since 1991.

An overview of the five meta-analyses shows that they relied on different groupings of studies depending on which studies were available at the time of the evaluation, the inclusion criteria used, whether studies of Interpersonal Psychotherapy were excluded from the mix, and how studies using different methodologies and measures were evaluated. Yet, even given these differences, they all concluded that brief psychodynamic psychotherapies produced very positive treatment effects compared to those obtained with patients left on waiting lists or given minimal treatment. The results were quite striking indicating that the average person treated with brief psychodynamic psychotherapy was better off than 80% to 90% of the untreated. The first meta-analysis, which included ill-defined therapies and studies with small numbers, yielded the most guarded conclusions (Svantberg and Stiles 1991). These investigators voiced concerns that the evidence—while supporting superiority over no treatment—did not show that the brief psychodynamic treatments were as good or as lasting as alternative treatments.

Prochaska and Norcross (2007) highlighted the consistent indications of treatment benefits from brief psychodynamic psychotherapy and noted the reservations that some researchers had about declaring brief psychodynamic treatment outcomes to be at least as good as those from other types of therapy such as CBT. They cited an “allegiance effect” in which research findings often reflect the biases or preferences of the researchers doing the study. It turns out, as they reasoned, that the small differences in outcome occasionally found between brief psychodynamic therapies and other treatments typically vanish when the researcher’s allegiance is statistically factored into the computation. For example, they point to the methodologically rigorous studies that were included in the meta-analysis performed by Leichsenring et al. (2004). This analysis accounted for elements like investigator allegiance and still discovered strong positive outcome effects for psychodynamic approaches and documented equal effectiveness in comparisons with other therapy models.

It can now be added that the most up to date meta-analysis done as a Cochrane review (Abbass et al. 2006) and which included only randomized, controlled studies continues to show the value of brief dynamic psychotherapy across a wide range of common mental disorders. Measures of depression, anxiety, and somatic symptoms all show evidence of treatment gains. Individual studies also reveal benefits as varied as weight gain in anorexia nervosa, improved interpersonal relationships, and reduced self-injury. Further, brief dynamic psychotherapy maintained or improved gains in long-term follow-up, which was up to 4 years. Parallel results have also been published by Leichsenring and colleagues (2006) who, after acknowledging that there are more studies of cognitive-behavioral therapy than psychodynamic therapy, went on to list thirty-two studies of psychodynamic psychotherapy with specific mental disorders that used controlled randomized trials and treatment manuals. These studies provide evidence of efficacy for psychodynamic psychotherapy in treating a broad range of conditions. For example, Milrod and her colleagues (2007) presented a study in which 49 adult patients with panic disorder were randomized to receive either a manualized panic-focused psychodynamic psychotherapy or an applied behavioral relaxation treatment. patients was delivered twice a week for 12 weeks. Outcome was rated by independent blinded evaluators. Subjects in the psychodynamic treatment experienced a significantly greater decline in severity of panic symptoms, lower treatment dropout rates, greater reduction in impairment and a higher response to treatment at termination (73% versus 39%). (See Table 89–3)

We do not have enough evidence yet to know if the findings from the well-controlled experimental studies generalize to patients seen in routine clinical practice. Another question revolves around the issue of what accounts for the positive results with seemingly different treatments. Consistent indications of parity in outcomes among different therapy approaches raises the possibility that factors common to the different treatments—such as the establishment of a positive treatment alliance—may be more important than their differences in creating positive change (Greenberg 2004a, 2004b, Smith et al. 1980, Wampold 2001). Toward the end of his career, when considering the results of his treatment approach, Freud wrote, “I do not think our cures can compete with those of Lourdes. There are so many more people who believe in the miracle of the Blessed Virgin than in the existence of the unconscious” (Freud 1933, p. 152). Today, a look at the data about 75 years after Freud’s comment reveals that considerable progress has been made. Freud should be reassured that the scientific evidence shows the treatment he created has been streamlined and found to offer significant relief to many dealing with emotional and somatic discomforts.

Models of Brief Psychotherapy

Brief therapies cluster within three broad models: relational, learning, and contextual (Steenbarger 2002). These differ in their understanding about the causes of presenting problems and the techniques necessary to alter them (Table 89–4).

Relational Therapies

Relational therapies include short-term psychodynamic treatments and interpersonal therapy (IPT). Their essential assumption is that presenting problems reflect difficulties in significant relationships.
Brief psychodynamic therapies

Brief psychodynamic therapies as do all psychodynamic therapies, postulate that presenting problems of patients result from an internalization of conflicts from earlier, significant relationships. Defenses fend off the anxiety from these conflicts and aid short-term coping. However, this prevents the conscious working through and mastery over these core relational issues. These issues re-emerge in future relationships whenever similar anxiety and conflict is experienced, triggering old patterns of defense, which are now no longer appropriate to the current relationship. This creates a secondary conflict and the consequences that typically bring people to therapy. The psychodynamic therapist understands that these presenting problems are the result of outmoded, currently maladaptive (defensive), efforts in the face of repeated interpersonal conflict.

Traditional (long-term) psychodynamic therapy works backward from presenting complaints to underlying core conflicts, using interpretation as a primary technique to promote insight into outmoded defenses and repeated intrapsychic and interpersonal struggles. The therapeutic relationship becomes the locus for such insight, as those struggles are reenacted in the transference relationship. As patients replay their maladaptive defensive patterns and interpersonal struggles within sessions, the dynamically oriented therapist engages the real relationship—the mature alliance between the self-observing patient and the therapist—to help the patient become aware of what is happening and why. With this insight into repetitive patterns and their consequences, patients can then attempt to rework the ways in which they handle interpersonal threats within the safe confines of the helping relationship.

Since traditional psychodynamic therapy requires the interpretation of unfolding historical patterns within the therapeutic relationship, with insight as the goal, such therapy often spans months, if not years, of analysis. Brief psychodynamic therapy has added several features that enable it to accelerate change:

1. **Circumscribed, here-and-now focus.** Brief dynamic therapy narrows the focus on “core conflictual relationship themes” (Luborsky and Mark 1991) that represent “cyclical maladaptive patterns” (Binder and Strupp 1991), which link current, past, and therapeutic relationships. While the past powerfully informs these conflictual themes, brief dynamic work actively focuses on highly salient, present-day manifestations of the cyclical patterns.

2. **Patient selection criteria.** Brief treatment is not appropriate for all patients and disorders. Patients who are experiencing emotional discomfort, can easily form a trusting relationship, and are willing to view problems in an interpersonal context, are helped the most (Levenson 2004).

3. **Active provision of positive relationship experiences within the therapy.** Brief dynamic therapists may rely primarily on interpretation e.g., Davanloo, but also foster change by becoming involved in the core relationship patterns, and by breaking the cycles of repetition by providing responses different from those anticipated by patients i.e. corrective emotional experiences (Levenson 1995).

4. **Creation of heightened emotional contexts for change.** Change can be accelerated by creating an enhanced state of experiencing among patients (Sifneos 1972, Davanloo 1980). Such anxiety-provoking therapies seek to challenge and break through patterns of defense/resistance. Under these emotionally charged conditions, patients more readily gain access to memories, impulses, and feelings associated with core conflictual patterns, facilitating an accelerated working through of these experiences within therapy.

In short, brief dynamic therapists play an active role, sustain a narrowed treatment focus, initiate interventions to challenge maladaptive defensive patterns and provide new, corrective emotional experiences. (See vignette). This markedly abbreviates the traditional length of psychoanalytically oriented psychotherapy but this brief therapy often extends to 20 or more sessions. Research studies emphasize that relationship factors, persuasion, suggestion, catharsis, and the therapist as a model are important in both brief and long-term psychodynamic therapies (Eisenstein et al. 1994, Fisher and Greenberg 1996, Wallerstein 1986, 1989).

Interpersonal therapy

Interpersonal therapy (IPT) began in 1984 as a brief, manualized treatment that has been successfully applied to a variety of presenting problems and interpersonal concerns (Stuart and Robinson 2003). As in psychodynamic therapy, IPT also addresses relationship issues and restricts patients, generally to mood and anxiety disorders, but abbreviates treatment even further by not making the therapeutic relationship a primary focus.

### Vignette

Gina, a 32-year-old trader, was successful working in the “pits” of the exchange, but had difficulty transitioning to electronic trading, where she felt socially isolated and unsure. For the first time, she failed to make money over the prior two quarters and reported being anxious, worried, with interrupted sleep and a lessened interest in socializing. She said it was “humiliating” to feel like a beginning trader at her age.

Gina’s personal and family history was negative for psychiatric disorders. She had strong support from family and friends. She was too “proud” to accept help from others and entered therapy reluctantly.

In initial sessions, Gina described a close relationship with her parents. Her father, protective, conservative, and difficult to please; was disappointed when she pursued trading rather than graduate school. Gina was never good enough for her father. She also did not want to be like her nurturing but submissive mother, without a career and dependent on a husband. During college, Gina briefly consulted with a psychologist when her grades fell precipitously; once she realized she could not maintain all As, she stopped attending classes and, despite heroic efforts late in the semester, did poorly. She could not face her family and experienced herself as a failure. She only righted herself academically once her parents indicated that her happiness was more important than her grades—a turning point in her relationship with her parents.

Gina was displeased with exploration of her past and insisted she only needed direct advice regarding her trading
IPT seeks brevity by establishing a narrow treatment focus in the interpersonal life of the patient, generally focusing on role changes or difficulties that the patient is experiencing in relationships: grief, interpersonal disputes, role transitions, and interpersonal sensitivity. IPT emphasizes attachment styles, changing patterns of communication, altering expectations within relationships, and using social supports to help patients deal with interpersonal crises (Stuart 2004, Weissman et al. 2000). IPT focuses on current relationships and how these can be better handled. These potential solutions form the basis for between-session efforts by patients, securing their active involvement in treatment. Subsequent sessions review and refine these efforts, casting the therapist in the role of an active, collaborative problem solver. Although IPT is sometimes included under psychodynamic therapy, particularly in some reviews of outcomes research, it is not a dynamic therapy and there are distinct differences (Markowitz et al. 1998). In IPT, resistances to change are dealt with in a straightforward manner by the therapist, not as pattern reenactments to be interpreted and worked through. Lengthy explorations of past relationship conflicts, transference relationships and reenactment of past interpersonal patterns are downplayed. As a result, IPT tends to be briefer than most short-term psychodynamic therapies, with treatment for depression ranging from 12 to 20 sessions (Stuart 2004). The goal of therapy is to promote independent functioning, as well as symptom relief. As Stuart and Robertson (2003) emphasize, IPT, unlike other therapies, does not presume a complete termination of therapy at the end of treatment. Rather, there is an assumption that future sessions may be necessary to maintain gains and prevent relapse.

In sum, the relational model of therapy achieves brevity by carefully selecting willing patients who readily form a therapeutic alliance, have a circumscribed problem, and are able to sustain their focus on this problem. Whereas the role of the therapist is different in short-term dynamic therapy compared with IPT—a significant other, as opposed to a collaborative problem solver—the ultimate goal is similar: altering problem patterns by generating new, constructive relational experiences.

Learning Therapies

Learning therapies, which include a wide range of cognitive-behavioral therapies, start from a different set of premises from the relational therapies. The presenting concerns of patients are viewed as learned, maladaptive patterns that can be unlearned. Moreover, patients are seen as capable of acquiring new, adaptive patterns of thought and action through skill development. As a result, the learning therapies feature the therapist in an active, directive, teaching mode and the patient as a student. This structuring of the helping relationship lends itself to active skill rehearsal within sessions and directed homework between meetings. The combination of tight learning focus and active practice of techniques ensures that most learning therapies are short term by their very nature.

It is helpful to distinguish between primarily behavioral treatments that emphasize exposure and cognitive approaches that target dysfunctional patterns of information processing for restructuring. While each can be
practiced in the pure form, there is often significant overlap, which affects the conduct and brevity of treatment.

Behavioral (exposure) therapies
Exposure-based behavior therapies are particularly effective in the treatment of post-traumatic stress disorder, obsessive-compulsive disorder (Hembree et al. 2004) and panic disorder (Barlow 2002). During assessment, patients may keep detailed logs that track the appearance of symptoms and the circumstances that trigger them. Concurrently, therapists educate patients regarding the learning model, explaining how and why symptoms appear. This can be highly reassuring for patients suffering from such disorders as panic, who may be bewildered by their symptoms.

Early in treatment, behavior therapies introduce specific skills designed to help control symptoms. These can include efforts at relaxation, thought stopping, self-reassurance, and seeking social support. Typically, skills are introduced one at a time, explained in detail, modeled by the therapist, and rehearsed in session by patients. Once patients master skills in session, they rehearse them as part of between-session homework.

Triggers for presenting symptoms are then deliberately introduced into therapy sessions via imagery and in vivo exercises. Patients are thus required to actively employ their coping skills while they are exposed to the very stimuli that have provoked symptoms. For example, a patient who has a compulsion to touch the door knob three times to magically ward off danger before he can leave a room is prevented from doing so i.e. response prevention. After imagining it in sessions, a patient who was assaulted in a parking garage returns to the scene with the therapist. In both these examples, the escalating anxiety is treated with relaxation exercises. A patient with panic disorder might simulate panic experiences by spinning in a chair, then utilize cognitive and relaxation skills to maintain composure. This real-life exposure provides patients with firsthand, emotionally powerful experiences of mastery, which accelerate the pace of symptom resolution. After one symptom is mastered, these skills are used to challenge and master a variety of symptom-related cues. Patient needs and variations in technique dictate whether exposure is progressively incremental or in a more rapid intensive fashion (“flooding”). This significant immersion into anxiety-arousing situations, often over many hours, can be beneficial (Hembree et al. 2004). Exposure appears to be effective because it allows patients to reprocess cues associated with distress (Shapiro 1995).

Cognitive therapy
Cognitive reprocessing therapies are now applied to a wide range of disorders, including depression, anxiety, eating disorders, personality, child and adolescent disorders and even schizophrenia (Hollon and Beck 2004). Cognitive therapy postulates that symptoms are due to automatic thought patterns that distort information processing about self, others, and the future (“cognitive triad”). Therefore, therapy attempts to identify these negative thought patterns, challenge them, and replace them with more constructive alternatives (Beck 1995). Time efficiency is obtained by combining in-session rehearsal and out-of-session homework.

Akin to behavior therapy, cognitive restructuring treatments begin with an assessment and psychosocial education. This education teaches patients the relationship between thoughts and feelings as well as ways in which automatic thoughts can sustain unwanted patterns of emotion and action. Cognitive therapists engage patients in a highly collaborative manner, minimizing resistances and sustaining the helping alliance.

Patients maintain a “dysfunctional thought record” in which they track events, reactions to those events, and mediating core beliefs. The main negative beliefs are of being helpless or unlovable (Beck and Bieling 2004), which distorts cognition by forming schemas that filter and darken future perception. The dysfunctional thought record is then used to create cognitive conceptualizations of patients, linking core beliefs to automatic thoughts, emotions and behaviors. The record also helps patients to recognize distortions as they are occurring and to appreciate their role in maintaining presenting symptoms. These specific cognitive distortions become a focus for intervention.

A primary technique in cognitive therapies is a Socratic process of guided discovery between therapist and patient, which raises doubts about the validity of these distortions and encourages a consideration of alternate construals (Beck and Bieling 2004). This process is also encouraged between sessions, as patients are asked to utilize thought records to evaluate their own degree of (dis)belief in the distortions. Each dysfunctional thought pattern is viewed by therapist and patient as a hypothesis to be questioned and tested. Behavioral experiments devised during sessions are carried out between meetings to provide direct, experiential tests of patient assumptions. The goal of this “collaborative empiricism” (Beck 1995) is to create vivid experiences of disconfirmation for patients, which aid the building of new, accurate schemas.

In summary, behavioral exposure therapies seek to extinguish specific conditioned responses in a very narrow focus; the cognitive restructuring therapies seek to establish a collaborative relationship that evaluates and restructures a range of dysfunctional cognitive patterns. Therefore, behavioral treatments tend to be brief—often lasting less than 10 sessions—than the cognitive therapies, which typically range between ten and twenty visits. Interestingly, Leichsenring et al. (2006) note that in Germany CBT for outpatient averages 40–60 sessions. Despite these differences, these learning therapies have many commonalities. They are highly structured and focused, with active assignments during sessions and “homework” in between. Learning therapies achieve brevity by replacing verbal exploration with experiences of mastery that directly challenge and undercut dysfunctional patterns with a powerful immediacy.

Contextual Therapies
A third, contextual, model of brief therapy stresses the ways in which presenting problems are situated within—and sustained by—their psychosocial contexts. Whereas the learning and relationship models stress internal sources of symptoms from the individual’s history, the contextual approaches to short-term work emphasize here-and-now factors that sustain initial problems. For instance, brief couples therapies view problem patterns as sustained by the reciprocal contributions of each partner (Baucom et al. 2004). Because situational influences are deemed central to the maintenance of problems, targeted problem-solving interventions are
designed to alter these situations. Such a tight focus helps to ensure that the contextual modalities are among the briefest of therapies.

We can identify two major strands of contextual theory in brief therapy: the strategic therapies and solution-focused therapy.

Strategic therapies
Strategic therapies evolved from the work of Milton Erickson. These include single-session treatments (Hoyt et al. 1992, Talmon 1990), as well as targeted treatments of several sessions. An important premise of the strategic therapies is that patients attempt to solve problems on their own. Many times, these attempts at solution contribute to an exacerbation of the initial concerns, creating self-reinforcing patterns (Rosenbaum 1990). A person who is anxious about being rejected in relationships, for example, might become guarded in a social setting. This could easily cause others to keep their distance, creating a self-fulfilling prophecy of rejection and isolation. In this case, the interpersonal context is a central part of what keeps the problem pattern alive.

Many times, the strategic therapist will attempt to break the vicious cycle by encouraging a reframing of the context (Fisch et al. 1982) and assigning directed tasks (Levy and Shelton 1990) that disconfirm patients’ worst fears and expectations. For instance, the therapist might draw upon a conversation with the patient about “procrastination” and frame the avoidant response as procrastinating about making social contacts. This opens the door to new ways of viewing the presenting problem, which, in turn, can help generate new action patterns. Such framings form the basis of directed tasks to break the self-reinforcing cycle, perhaps by challenging procrastination and taking doable initial steps to converse with others. The goal of strategic intervention is to catalyze initial change that patients can sustain independently. The goal is not to effect fundamental personality changes or overhauls in global cognitive or interpersonal processes. For this reason, strategic therapies are highly abbreviated by design.

The initial interview of strategic therapy does not yield a diagnosis or a formulation of personality, but a description of the present contextual factors that help to maintain the patient’s presenting concerns. This description includes the people involved in the patient’s symptoms and the roles they take; the patient’s view of the situation; the sequence of behaviors that result in complaints; and the specific contexts in which these complaints arise (Rosenbaum 1990). From this conceptualization, therapists gain an appreciation for the ways in which patients feel stuck in their attempts at resolution. Very often, the conceptualization will also suggest ways of disrupting problem cycles and encouraging new actions in old situations.

As Rosenbaum (1990) stresses, the goal of the therapy is not to find a solution for a patient’s problem, but to create a situation that lends itself to spontaneous goal attainment. The aforementioned patient who is afraid of social interaction, for instance, might access wholly new behaviors to combat “procrastination” rather than “anxiety.” When these new behaviors achieve patient goals, they can be accessed repeatedly, creating positive behavior patterns and a virtuous problem/solution cycle. In this sense, strategic therapy is a process for removing barriers to change and not a self-contained change process in itself—a factor that contributes significantly to its brevity.

Solution-focused brief therapy
An offshoot of strategic therapy, solution-focused therapy (SFBT) provides a somewhat different contextual approach to short-term change. SFBT’s essential hypothesis is that people are continuously changing, enacting solution patterns as well as problem ones. Indeed, for the solution-focused therapist, there is an important sense in which problems do not exist at all. When patients cannot reach their goals, they eventually construe that they have a problem. This reification (the notion that the problem is something they “have” as part of them) becomes self-fulfilling. As patients become more focused on their “problem” and ways of solving it, they unwittingly reinforce the distress that comes from feeling beset by problems. Most important, the problem focus blinds patients to their strengths and those occasions in which they do, in fact, attain their goals. It is the immersion of patients in a problem focus and not the independent existence of problems themselves that sustain presenting concerns.

The goal of SFBT is to break this immersion by focusing on solution patterns rather than problems. In a sense, SFBT is as much an epistemological intervention as a psychological one. The initial assessment asks patients to identify positive pre-session changes. The idea is to make these a scaffold upon which further adaptive efforts can be built (Walter and Peller 1992). There is also an initial effort to steer patient consideration toward occasions in which problems either do not occur or occur less often, as these may contain the kernels of adaptive capacities. “What, specifically, were you doing to get your work done without procrastinating on this occasion?” Enacting these exceptions to problem patterns—doing more of what is already working (deShazer 1988, O’Hanlon and Weiner-Davis 1989)—is the focus of therapy. Exploration of problem patterns and even skills-teaching to address problems are minimized, because these would only add to the patient’s own immersion in a problem-based mindset. Because SFBT does not seek to initiate new behavior and thought patterns but instead builds upon existing ones, it tends to be a highly abbreviated treatment, lasting several sessions on average (Steenbarger 2004).

Solution-focused therapists stress a high degree of collaboration with patients to avoid resistances to change. This is accomplished through mutual goal setting, highlighting goals that are positively framed, concrete, and behavioral. Only once there is an agreement upon the specific aims of the therapy do the participants engage in an exploration of how the patient may already be achieving the goals in some measure, on some occasions. Homework assignments accomplish much of the “do more of what is already working”; these also are developed collaboratively, avoiding resistances that would unnecessarily extend the change process. The emphasis is upon here-and-now goal attainment and actions that can bring such attainment, further contributing to the brevity of SFBT.

One way in which SFBT differs from strategic therapies is that it lends itself to manualization. SFBT manuals (deShazer 1988, Walter and Peller 1992) view therapy as a series of steps:
Common Therapeutic Factors

- Identification of pre-session change e.g., “many people feel a little better between making the appointment and coming here for the first time. Have you noticed any positive changes?”
- Use of the “miracle question” e.g., “Suppose that one night, while you sleep, there was a miracle and this problem was solved. How would you know? What would be different? How would your husband know without your saying a word to him about it?” (deShazer 1988, p. 5)
- Formulation of solution-based goals e.g., I will put myself into two situations this week in which I have to introduce myself socially.
- Scaling questions to elicit exceptions to patient complaints e.g., “On a scale of 1–10, where 1 is “constant bickering” and 10 is “perfect harmony,” how would you rate your relationship over the past week?”
- Provision of feedback to support change
- Assignment of tasks to facilitate the generalization of solution patterns e.g., “Standing up for yourself worked well for you. You let your father know exactly what you were thinking and feeling in a polite, constructive way. Perhaps that is something you can try with your brother as well and see what happens.”

Like the strategic modalities, SFBT relies less upon verbal exploration and more upon direct experience to break circular patterns. The goal of both is not so much to resolve a problem as to help patients see that what they took for their world.

Factors Common to the Brief Therapies

The various brief psychotherapies—including behavioral, cognitive, interpersonal, short-term psychodynamic, strategic, and solution-focused—make different assumptions about the nature of presenting problems and their treatment (see Dewan et al. 2004 for an overview). Nevertheless, a host of common ingredients make these approaches to change more similar (Greenberg 2004a, 2004b) than differences in their underlying theories might suggest. In fact, factors common to all long- and short-term models account for a significant proportion of the variance in patient change. (Lambert and Ogles 2004, Wampold 2001) See Table 89–5.

Table 89–5  Common Therapeutic Factors

| • A strong therapist–patient alliance |
| • Opportunity to confront and face problems |
| • The development of patient mastery experiences |
| • Facilitation of patient hope, positive expectations of the future |

Some of the common ingredients found across the brief treatments and their role in accelerating change include the following:

Time-Effectiveness

All brief therapies make time an explicit part of treatment planning. Some, such as IPT, are time-limited, allotting a fixed number of sessions at the start of treatment. Others allocate sessions as cases progress, balancing two concerns for effectiveness and efficiency. The actual duration can vary considerably. Strategic and solution-focused therapies of several sessions—and even a single session (Talmon 1990)—are not uncommon. Behavioral treatments often are completed within 10 sessions, but cognitive therapy may take 10–15 visits. Brief dynamic therapies of 20 sessions—or more—are common. Given such variation, it is difficult to say that time itself is a common ingredient of the brief modalities.

Linking these approaches, however, is the value of efficiency in the change efforts. Budman and Gurman (1988) have used the term “time effective” to capture the brief therapist’s concern with maximizing the use of time during and between treatment sessions. This time-effective mindset entails several values, including an emphasis upon circumscribed change efforts over global, personality change and encouragement of short, intermittent helping through the lifespan (Cummings and Sayama 1995). For these reasons, applications as diverse as dialectical behavior therapy for borderline patients (Linehan et al. 2001); short-term dynamic therapy for relational concerns (Levenson 2004); and solution-focused therapy for the problems of families and couples (Walter and Peller 1992) are considered to be time-effective, although these will not be equally brief.

The absolute brevity of a therapy is a function of outcome measures utilized, presenting problems, goals sought in treatment, and the patient’s readiness for change (Steenbarger 1994). Enhanced well-being and symptom relief typically occur earlier than functional change at work and in relationships, suggesting that therapies seeking the latter (which typically include cognitive, interpersonal, and short-term dynamic modalities) will tend to be lengthier than their behavioral, strategic, and solution-focused counterparts.

The time-effective therapist is thus less bound by absolute session durations, focusing instead on the process of change and ways in which it can be accelerated. Most of the remaining common factors discussed below help to achieve this end by targeting changes and encouraging concentrated, intensive work on these.

Patient Inclusion Criteria

Brief treatment—certainly that of less than 20 sessions—is not equally effective for all patients and presenting problems. Anderson and Lambert (2001) reported that patients with more severe presenting issues took longer to achieve clinically meaningful gains than those with more benign presentations. Overall, it took 13 sessions for half of all patients in their study, and over 50 sessions for 75% of them, to reach a level of clinically significant change. Interestingly, Lambert and Ogles (2004) found that it takes 21 sessions for highly dysfunctional patients to achieve meaningful clinical change; those with characterological difficulties required about a year of treatment, suggesting a dose-response relationship based on differences in severity.

When patients are in the action phase, i.e. ready for change, aware of problem patterns and motivated to take action to deal with these—therapy is generally briefer than when patients are unclear about their problems and ambivalent about change (Steenbarger 1994). The latter, precontemplative or contemplative patients (Prochaska and Norcross 2002),
need time to explore their patterns and their consequences, necessarily adding to the duration of treatment.

What this means in practice is that abbreviated treatments are appropriate for some patients and problems and inappropriate for others. Accordingly, all brief therapies attempt to implement inclusion/exclusion criteria during the initial phase of treatment using their own specific criteria. Summarizing the clinical literature in brief therapy, Steenbarger et al. (2004) identify six common inclusion criteria that form the acronym DISCUS.

- Duration of the presenting problem is relatively recent, not chronic.
- Interpersonal history of the patient reveals the ability to sustain meaningful relationships.
- Severity of presenting problems is mild to moderate, not impairing the ability to sustain between-session and within-session work toward change.
- Complexity of presenting problems—the variety of symptomatic manifestations—is low, enabling patient and clinician to focus on a specific pattern for change.
- Understanding of problems and the need for change is high, enabling patients to begin work quickly and sustain motivation for change.
- Social supports outside of therapy are present, so that treatment does not have to serve a patient’s ongoing support needs.

Situations in which one or more of the DISCUS criteria are not present may still be addressed by time-effective treatments, although not ones that are highly abbreviated. The dialectical behavior therapy (DBT) of Marsha Linehan and colleagues (2001) is a good example of how short-term modalities, employed in sequence, can address the longer term treatment needs of populations with more chronic, severe impairments.

**Focal Aims**

Personality reconstruction is a common goal of time-unlimited psychoanalytic therapies. Brief treatments typically seek more circumscribed aims. Indeed a common ingredient of the short-term therapies is an initial assessment in which presenting complaints are formulated as focal patterns that can be addressed in a concerted manner.

Examples in the short-term dynamic therapies are referred to as cyclical maladaptive patterns (Binder and Strupp 1991, Levenson 2004), or core conflictual relationship themes (Luborsky and Mark 1991). Malan (1976) and Davanloo (2001) conceptualize these as “triangles of insight,” linking past, present, and helping relationships and characterized by warded-off impulse-feelings that are defended against in the face of anxiety (Figure 89–1).

In interpersonal therapy, the focus is on problem areas such as grief and loss, interpersonal disputes, role transitions, and interpersonal sensitivity (Stuart 2004). Cognitive therapies (Beck 1995, Beck and Bieling 2004) frame presenting concerns as dysfunctional schemas; patterns of automatic thought that distort perceptions of self, others, and the future, the “cognitive triad.” Behavioral treatments (Hembree et al. 2004) stress sequences of situations and responses, focusing on the unlearning of maladaptive conditioned patterns and the learning of new, adaptive ones.

Strategic therapies focus on patterns of problems and attempted solutions in which the latter unwittingly reinforce the former (Rosenbaum 1990). This emphasizes here-and-now patterns, rather than ones that link past and present. Solution-focused therapies (Steenbarger 2004) minimize a problem focus altogether, instead channeling therapeutic efforts toward exceptions to problem patterns that capture patient strengths. Indeed, it might be said that the solution-focused treatments find their aims in client goals, rather than problems.

Perhaps the most important function of the treatment focus in brief therapy is its ability to help patients make sense of their problems and see themselves in a novel light (Steenbarger 2006). This opens the door to new, positive patterns of thought and behavior that, with repetition, can be internalized. Such novelty helps to create the “corrective emotional experiences” (Alexander and French 1946) that appear to be central to the short-term therapies (Budman et al. 1992).

**Therapist and Patient Activity**

Whereas such time-unlimited therapies as client-centered treatment and psychoanalysis tend to be nondirective, encouraging patterns to unfold on their own, brief therapies tend to be more active and directive. Working with a limited number of sessions and emphasizing efficiency as well as effectiveness of change, both brief therapists and their patients are expected to become actively involved and maximize the use of time both within and between sessions.

The work of Sifneos (2004) and Davanloo (2001) illustrate therapist activity within sessions. Both provoke patient anxiety by directly confronting resistances to change and defenses against impulses and feelings. Such active confrontation heightens patient experiencing, which triggers access to fresh memories and perspectives that yield the aforementioned corrective emotional experiences. Levenson (2004) stresses the role of the therapist in providing new relationship experiences for patients, so that cyclical maladaptive patterns can be disrupted and revised. Many times, this requires responding to patients in unexpected ways. For instance, a therapist may respond to a patient’s attempts to push the therapist away with empathy and understanding, rather than defensiveness, encouraging a different way of handling fears of rejection.

Behavioral (Hembree et al. 2004) and cognitive therapies (Beck and Bieling 2004) require patients to be actively involved in change efforts between sessions as well as within. Both rely heavily upon assigned tasks to face and challenge existing problem patterns. Behavioral treatment, for example, may stress in-session exposure to stimuli that provoke presenting symptoms, creating direct experiences of mastery. This exposure work continues between sessions to make maximal use of time and to cement initial changes. Similarly, cognitive therapies stress the collaborative exploration of problem patterns (Beck 1995), with the therapist providing Socratic challenges to dysfunctional thought patterns. These challenges serve as a model for clients to interrupt and alter their own automatic thoughts, particularly during between-session exercises. With repetition, individuals internalize new ways of processing information about themselves and the world, generating fresh schemas.

A similar structuring of between-session experiences can be found in interpersonal therapy. Stuart (2004) notes...
that maintenance of a high level of emotional experiencing is crucial to sustaining the motivation to change, requiring therapists to focus on emotions associated with both the process of treatment and the content of what is being discussed. Within sessions, the therapist helps patients explore their patterns of communication and relatedness and how these might be interfering with the meeting of interpersonal needs. Between sessions, the patient is encouraged to try alternate modes of communicating and relating, actively using current relationship contexts as opportunities for change.

A somewhat similar emphasis on the completion of therapeutic tasks underlies strategic and solution-focused brief therapies as well. In the strategic modalities, the therapist may prescribe tasks that interrupt self-perpetuating cycles of problems and attempted solutions (Rosenbaum 1990). Drawing upon the work of Milton Erickson, for example, Haley (1984) describes how clients can be prescribed “ordeal” tasks that require them to deal with their life situations in novel ways. In solution-focused work (Steenbarger 2004), the therapist helps patients discover exceptions to problem patterns—ways in which they are already meeting personal goals—they are encouraged to do more of it through assigned exercises (Walter and Peller 1992).

In sum, the brief therapies represent doing approaches to change. Relatively less emphasis is placed upon the exploration, insight, and catharsis emphasized in many time-unlimited treatments. Instead, priority is accorded to the provision of in-and-between-session activities that disrupt, challenge, and replace existing patterns of thought, feeling, and action. This places both therapists and patients in the role of change agents, actively generating novel, positive experiences that can become part of an ongoing repertoire.

Sequencing of Change
The brief therapies are similar, not only in their aims, but in their structuring of the change process. Steenbarger et al. (2004), reviewing the brief psychotherapies, note that they follow a common three-phase course:

- **Engagement.** An introductory period of collaborative exploration, rapid alliance formation, and establishment of focal aims. During the engagement period, the brief therapist helps patients view their presenting concerns through new lenses, clearing the way for both optimism regarding change and for new action patterns. The various schools of short-term therapy serve as different lenses that enable patients to make sense of their concerns and gain a sense of mastery over these.
- **Discrepancy.** During the second phase, the therapist creates novel experiences that undercut presenting patterns and encourage the generation of new ones. This typically involves a heightening of affect within the therapy and the provision of new insights and tasks. Indeed, the chief aim of the brief therapies is the provision of new, positive experiences under altered emotional states that facilitate learning and internalization.
- **Consolidation.** In the final phase of brief therapy, the role of the therapist is to sustain initial changes by creating a series of experiences that reinforce new patterns. Without consolidation, initial changes are apt to be followed by relapse (Steenbarger 1994) and an important limitation on the absolute brevity of treatment. Therefore, many of the brief therapies extend their limited sessions by spacing them over a lengthy period once initial changes have been achieved. This permits therapy to remain brief in terms of the number of sessions, but also retain much of the advantage of longer term work, in which changes become internalized.

In their change methods and structuring of change, the brief therapies are not so much different from their longer term siblings as intensifications of these. By stressing the factors that are crucial to the success of all the major therapies and becoming more intentional in their incorporation into treatment, therapists are able to accelerate change for selected populations. They accomplish this by focusing on limited aims and actively creating in-session and between-session environments that are conducive to experiential learning.

Conclusion
As early as 1995, a review by Messer and Warren found that 84–89% of patients were treated in less than 20 sessions, 63–76% in under 10 sessions, and 34% in 1–2 sessions. “The conclusion is clear,” they wrote. “Most people receive brief treatment, whether in public or private settings” (p 7). Consistent with this, they found that “the research literature indicates that most clinicians conduct brief therapy and that it makes up a substantial percentage of their practice” (p 9). Since then—pushed by continuing financial pressures and aided by manuals for many of the brief therapies and applicability to an increasing range of disorders—the practice of brief therapy has grown and there is an increased emphasis on making therapy brief by design rather than by default.

For many nonpsychotic disorders, there is data supportive of robust efficacy of brief therapies when compared to placebo or to medications alone in terms of symptom relief and prevention of relapse. Brief therapies have also been studied in combination with medications, either simultaneously or sequentially, and found to be useful (Dewan and Pies 2001). The majority of carefully controlled studies involve CBT or IPT and are reviewed elsewhere in this volume (Chapters 88 and 91).

Therapist training and competence. Some of these studies also highlight a point that needs repeated emphasis: therapist training, competence, and experience matter. It has been shown that higher levels of training are correlated with greater improvement in patients’ symptoms and decreased rates of attrition and recidivism (Burlingame et al. 1989). Even this may not be enough. Several studies which used trained and certified therapists found that therapists who were independently rated as above average and therapists with greater experience had more positive outcomes. In one study, patients of the above average therapists did as well as the medication group, whereas patients of the below average therapists did only as well as the group on placebo (Elkin et al. 1995, DeRubeis et al. 2005). Clearly, even though the therapy is brief, optimal training is not. Therefore, self-study, week-end or short courses are not adequate (Burlingame et al. 1989). Messer and Warren (1995) and...
Strupp et al. (1988) emphasize that training courses must be extensive and carefully designed. They must not focus merely on the technical manual but must also pay attention to the common factors and interpersonal aspects crucial to all therapies. Ongoing training and supervised clinical experiences are critically important and are becoming increasingly offered by training institutes and professional organizations.

This is an exciting time for the field of brief therapy, with the clinical application of established treatments to new disorders (Milrod et al. 2007) and to increasing levels of severity as well as the introduction of creative new ways to be more time-effective. The next challenge is to distill this data for the benefit of a single patient, in order to best establish a base of common factors on which a specific therapeutic technique could be added to maximize real-world effectiveness for each patient.

Human beings live in a social world where their ability to gain self-esteem and self-definition significantly follows from their success in personal relationships. A psychotherapy group is a social arena where members can learn about their assets and deficits through interactions with peers (fellow members) and authority (the therapist). Members also have opportunities to experiment with new behaviors in the protected atmosphere of the group in preparation for using them in their external world.

A broad spectrum of theoretical approaches help therapists focus on varying aspects of group behaviors and interactions. Some focus on individuals as seen through the psychoanalytic lens of transference and resistance; others stress interpersonal transactions arising from childhood constrictions or distortions; still others focus on properties of the group as a whole, emphasizing group dynamics and systems theories as the central organizing concepts. Social learning principles are present in almost all orientations and are central to cognitive-behavioral approaches. Integration of these approaches has yet to be accomplished. Therapists may maintain a central theoretical orientation and pragmatically adapt elements from other orientations to address particular problems as they emerge during treatment.

This chapter primarily addresses outpatient work with adults in the psychodynamic tradition. Groups for specialized populations (e.g., persons with persistent and serious mental illness, trauma, and eating disorders) and behavioral group treatment formats are then discussed in separate segments of the chapter. A fuller explication of many of the topics in this chapter is contained in Rutan et al. (2007).

History

Joseph Pratt, an internist, who treated tuberculosis patients in organized classes, is generally credited with founding modern group psychotherapy. Most early contributors to group psychotherapy were schooled in psychoanalysis, which they modified for the group setting. Jacob Moreno emphasized action and spontaneity in founding a psychodramatic approach to treatment. S.R. Slavson, a self-taught psychotherapist, expanded his initial interest in children’s groups to adults and was a central figure in the founding of the American Group Psychotherapy Association in 1942.

Group therapy received a stimulus during World War II when many therapists were exposed to group work during their military experience. Theroreticians in England (Bion, Bridger, Ezriel, Foulkes, Rickman, and Sutherland) and in the USA (Horwitz, Glatzer, Lieberman, Scheidlinger, Schwartz, Whitaker, Wolf, and Yalom) applied psychoanalytic or interpersonal (Sullivanian) concepts to a rapidly expanding interest in group treatment.

Interest in group processes, stimulated by the work of Kurt Lewin, led to the educational experiments in group dynamics at Bethel, Maine. The social upheavals of the 1960s resulted in a burgeoning of sensitivity training experiences (T-groups) and a variety of personal growth groups. The emergence of transactional analysis, gestalt therapy, bioenergetics, existential models for group therapy, and many additional innovative variations have enriched the group therapy field.

Activity groups for children began in 1930 and later developed into verbal groups for children and adolescents. Groups for special populations have gained popularity and are used in schools to address issues such as parental divorce, substance abuse, and acquired immunodeficiency syndrome (AIDS) prevention. Short-term models are also widely applied to special adult issues, including psychological trauma, bereavement, and a host of medical and social situations. Such groups may be used with dynamic or behaviorally oriented formats. Time-limited psychoeducational groups, with an emphasis on imparting information and sharing experiences, provide additional therapeutic opportunities.

The self-help (SH) movement, which traces its origins to the efforts of Alexander Low and Recovery Inc. in the 1930s, and the emergence of Alcoholics Anonymous and the 12-step model, which is also applied to other addictions, have increased the awareness of the therapeutic potential of collective interaction in the recovery and maintenance of individual emotional well-being.

The future will continue to see the use of a broad spectrum of group modalities and a variety of different models as the entire psychotherapeutic field endeavors to find a balance between efficiency and effectiveness. For an excellent review of nine decades of group psychotherapy, see Scheidlinger (1994).

Group Therapy Theory

The theoretical spectrum informing the practice of group therapy is broad. Within psychodynamics, group clinicians...
embrace, either singly or in combination, drive, object relations, interpersonal, self-psychology, attachment, or systems theory (Freud 1955, Kibel 1992, Harwood and Pines 1998, Billow 2003a, Yalom and Leszcz, 2005, Rutan et al. 2007). Other therapists favor behavioral or cognitive-behavioral approaches. Transactional analysis, originating from the work of Berne (1966), and Gestalt therapy (Perls et al. 1951) emphasize interpersonal transactions arising from more traditional psychodynamic theory. In addition, group theoreticians are generally categorized along a continuum of group as a whole, interpersonal, and intrapsychic. There are few purists, and varying degrees of integration is the norm (Table 90–1).

A common thread in many of these theories is that individuals in their interaction and discourse within the group will exhibit their difficulties in relationships, which in turn provides a window into their internal world. In short, the group becomes a microcosm in which their inner world turns provides a window into their internal world. In short, the group will exhibit their difficulties in relationships, which in turn provides a window into their internal world. In short, the group will exhibit their difficulties in relationships, which in turn provides a window into their internal world.

A common thread in many of these theories is that individuals in their interaction and discourse within the group will exhibit their difficulties in relationships, which in turn provides a window into their internal world. In short, the group becomes a microcosm in which their inner world is displayed (Slater 1966).

**Group-as-a-Whole Approaches**

These theories emphasize whole-group processes as the primary therapeutic vehicle. They subscribe to notions that members are influenced by the group dynamics and that one or more persons may “speak” (verbally or behaviorally) for the entire group.

Bion (1960), working within a Kleinian object relations model, conceptualized groups as having two levels: work and basic assumptions. Work groups operate on a reality principle and are goal directed. Basic assumptions groups function as if the group were meeting to satisfy members’ emotional needs. Bion identified three basic assumptions that suffuse the work group: dependency, fight or flight, and pairing. Bion suggested that individuals have a basic tendency toward one of the basic assumptions with which they will enter group life. Therapists working in this model focus on members’ relationship to the leader, particularly as expressed through basic assumptions. Billow (2003b) has elaborated on Bionian theory in combination with relational theory, with greater emphasis on the contributions of the clinician to the therapeutic process.

Tripartite conflict models, in which an impulse, a wish, or an object need was met with a counterreaction or a fear leading to a compromise, were applied to group therapy by Whitaker and Lieberman (1964) (group focal conflict with the three elements: disturbing motive, reactive motive, and solution) and Ezriel (1973) (psychoanalytic group therapy with the three elements: required, calamitous, and avoided relationships). Therapeutic efforts are directed to elucidating the conflicts, thereby freeing up constricted solutions or avoided relationships.

Foulkes (1961) formulated group analysis, applying a figure-ground gestalt framework that emphasized analysis of communication and relationships network (matrix) among the members and with the conductor. The conductor’s (therapist’s) attention shifts between group and individual, with one representing the figure and the other the ground in the gestalt of the group interaction. This is the primary group therapy model in Europe and Israel.

**Interpersonal Approaches**

Elaborating on Sullivanian interpersonal principles of psychotherapy, Yalom and Leszcz (2005) have evolved a group therapeutic approach that focuses on the relational nature of emotional problems. In this model, the group setting provides patients opportunities to learn about their recurrent difficulties in developing and sustaining relationships. Members reenact and have opportunities to learn about and modify their previously acquired dysfunctional interpersonal and relational behaviors in the group microcosm where dysfunctional relationships are demonstrated as well as described.

The interpersonal group therapist works to create an environment where members’ creation of their outside world can be examined in a therapeutic atmosphere. The therapist steers the members to the-here-and-now focus, which is conceptualized as a two-tier integrated experience: the first element is the person’s experience in the immediacy of the therapy session—this takes precedence over members’ outside current life and distant past; the second is illuminating the process, by which is meant “[it] must examine itself; it must study its own transactions; it must transcend pure experience and apply itself to the integration of that experience” (Yalom and Leszcz 2005, p. 142). The process is formulated as helping members recognize their intentions and their impact on others, which illuminates how they are viewed by others and open opportunities to view their own self-regard. In the group, members explore their satisfaction with their habitual relational style and their motivation to change.

Group cohesion, a concept that speaks to the relationships among the members, with the leader, and with the group, is seen as essential for the therapeutic process.
Cohesiveness is not an easily delineated concept; it includes a sense of belonging to and valuing the group, a sense of feeling supported and accepted, an esprit de corps. Cohesiveness is not static. It may be enhanced as members feel that they are learning about themselves or they can be helpful to others, or it may be disrupted by interruptions in scheduled meetings or advent of new members. One of the key elements enhancing cohesion is members learning to give and receive feedback, a process linked to helping members learn about how they impact others and their own emotions in the process. In this respect, the group then comes to represent a healthy family in which conflict can be resolved and healing relationships exist.

In concert with other dynamic therapies, interpersonal group therapy (IGP) values norm building, including focusing on the here and now, taking responsibility for looking at one’s own behavior and its impact on the self and other, and examination of transferences (often described as parataxic distortions). Dynamic processes such as scapegoating, emotional contagion, and the impact of norms are carefully monitored. Whole group interventions are seen as useful when the group processes appear to interfere with learning. Linkages to the outside world and to the past help consolidate learning. Group dynamics are appreciated as impacting upon the individuals (additional interpersonal group therapeutic factors are discussed in the section below).

Intrapsychic Approaches
Intrapsychic theories are primarily application of dyadic theory into the group setting. The emphasis is on unconscious processes, with the group providing opportunities for patients to regress to a level of internal conflict or developmental arrest. These theories explore individual transferences, resistances, and developmental arrests as the primary therapeutic focus. Peers may be experienced as siblings or as displacement objects from parental figures (Siarson 1950, Wolf and Schwartz 1962). Groups may either dilute or intensify transferences to the leader (Horwitz 1994), which enables “stuck” patients to resolve impasses occurring in dyadic treatment. Regression is limited, and the presence of others creates a balance between the external and the internal worlds (Durkin 1964). Integration of an intrapsychic framework with that of the group as a whole is contained in descriptions of members’ transferences to the group as a preoedipal maternal experience (Scheidlinger 1974).

Gustafson and Cooper (1979) posited that individuals enter groups with unconscious and conscious plans to determine if they will be traumatized in the group as they had been in the (developmental) past. They present “tests” to determine if they will be attacked or to learn new ways of problem solving. Passing the tests enables patients to disconfirm old beliefs and to restart development.

General Systems Approaches
General systems theory is based on open systems theory (von Bertalanffy 1966). Emphasis is placed on the boundaries separating the group from the external world and members or subgroups from one another (Durkin 1981). Agazarian (1997) elaborated systems concepts into a model of group treatment that focused on subgroups as the primary site of therapeutic attention. She asserted that by focusing on subgroups, which contain individual differences and similarities, members are more prepared to address intrapsychic defenses and resistances.

A systems perspective highlights participants’ cultural background and the impact of such forces on conscious and unconscious values and attitudes (Ettin 1994). Similarly, events in the culture and “politically correct attitudes” may constrain or stimulate members and are transported into the consultation room often outside of awareness as a social unconscious (Hopper 2003).

Group Dynamics and Group Development
The basic science informing group treatment is group dynamics and development, an understanding of which allows the therapist to select and integrate interventions directed to individual, interpersonal, and intrapsychic levels of group process (Table 90–2).

Group Dynamics
Group dynamics is a study of the forces that shape a group as an “organism.” The group is examined from a different perspective than merely as a sum of individual dynamics. Dynamic processes are present in every group as it pursues its goals, with overt and hidden behavioral (verbal and nonverbal) rules (norms) and ideals (values), which constitute the group culture. For example, group norms are reflected in the “proper way” for latecomers to enter a meeting. In one group latecomers apologize for their tardiness, in another they provide an explanation, and in a third they quietly sit down. Many norms highlight positive “behaviors,” such as thinking about process, reflecting on one’s impact on others or on one’s experience in the moment. Other examples are sanctions on eating, drinking, or physical contact during the session. Less overt norms may limit emotional expression. Respect for others’ opinions and helping others would represent group values.

Each group develops its own culture. Individuals are influenced by their race, gender, age, religion, education, and the broader culture, including values of the family of origin, subculture, and the local and national identity. Group structures influencing the dynamics include size, frequency, and duration of the meetings. Illustrative of a broad cultural dynamic is the impact of the changing view of what is politically correct. Individuals must be aware of when and where
certain expressions may be spoken, because inadvertent gaffes may result in severe sanctions. In sum, group dynamics comprise a study of how the whole group functions.

Groups evolve specialized functions (roles), which serve to modulate the emotional climate and the work. Roles may be filled by a single person or by a number of individuals—from a whole group perspective, it is the function that matters. Four roles describe these functions: structural, sociable, divergent, and cautionary (MacKenzie 1997). The structural (leadership) role addresses group work. The therapist is the primary occupant of this role, but members also function in keeping the group on task. A structural leadership role might be a member’s comment that the group starts and stops on time or that the members are not addressing a member’s absence. The social (emotional) role helps contain or express feelings and assists in managing social relationships within the group. The role might be expressed by individuals who relieve group tensions by changing the topic, making a joke, smoothing ruffled feelings, or encouraging expression of less acceptable and/or painful feelings. A member might identify emotions, saying “perhaps we all might wish to avoid talking about the absence because we are so angry with the person.” The cautionary role is often filled by a silent member, or who speaks in generalities. These individuals represent the need for safety, but secretiveness may be felt as threatening. The divergent role is filled by persons who seem oppositional, who “don’t go along with the crowd,” or who seem to fight authority. They are likely to become a container for others’ unacceptable thoughts or emotions (projective identification). Such individuals are vulnerable to becoming scapegoated, a process in which inadmissible feelings are seen (or placed) in one person and thereby kept out of awareness in the others. Roles may also be seen in Bionian basic assumptions, where one person may represent a dependency or a fight-flight group. The concept of role helps clinicians maintain awareness of individuals and the group as a whole. As a way of thinking about roles, therapists may silently consider if the person is acting as an individual or fulfilling a group function.

Group Development

The seminal work of Bennis and Shepard (1956) produced a spate of studies demonstrating that groups have a natural developmental sequence. Groups must accomplish certain tasks as they move from a collection of individuals to a functioning and working organization. Group development is nonlinear, being subject to perturbations and reorganizations with regressive and progressive movement.

The concept of group development is an abstraction, roadmap, or guideline. Development is contingent on leadership function and on membership composition. Group developmental achievements are not always equivalent to individual’s therapeutic success. For some patient populations, treatment might be considered a success at earlier development stages (with only brief forays into more advanced stages), whereas optimal therapeutic benefit would not accrue for other populations until the group more consistently functioned at the later developmental stages.

Formative (Engagement, Orientation) Phase

In a typical psychodynamic therapy group in which expectations are to expose hidden shameful or guilty secrets, members in efforts to feel protected and to gain information may turn to the therapist for guidance, similar to looking to a parent or teacher. They may become dependent or idealize the therapist as all-knowing, hoping for simple procedural formulas. Alternatively, they may alleviate anxiety by searching for similarities with other members by asking seemingly superficial questions: Where were you born? Do you work? Are you married? They may self-stabilize by remaining silent or testing the limits of behavior. These latter attempts include various oppositional or “difficult” behaviors, including persistent demands for topics to discuss, dominating the conversation, suggesting facile solutions to problems, and being impervious to observations about one’s own behavior or to the impact of behavior on others.

In the formative phase, the therapist orient members on how the group will function by trying to understand the meaning of various behaviors, primarily within the here-and-now of the meeting. Interventions may be addressed to individuals, subgroup, or the group as a whole. Cohesion is fostered by highlighting common themes or concerns, wishes for protection or guidance, and fears of criticism or humiliation.

Gradually members verbally and behaviorally reveal themselves, all the while monitoring “safety.” In this process norms emerge, which contain anxiety and set standards for acceptable behavior. As the process continues, members learn that the leader is not omniscient or omnipotent. They discover that they can contribute to the process and understanding of one another. In this formative phase, members may learn a good deal about how they meet strangers and what promotes or undermines feelings of safety. They have experiences helping them understand how they manage anxieties with newcomers and look to or reject authority.

Reactive (Power, Differentiation) Phase

The reactive phase is characterized by periods of conflict and intense emotions. Threats to quit are common and at times acted on. Two elements contribute to this phenomenon. First, group membership means abiding by rules (initial norms may feel restrictive), which activates protest. These behaviors serve to modify restrictive norms, providing for greater flexibility. Second, members compete for leadership, which can become quite intense.

The therapist is subjected to considerable stress during this phase. As “author” of group treatment, he may feel bombarded and ineffective. The clinician’s ability to understand the criticisms as members’ antidote to frustration, powerlessness, or diminished control helps maintain his/her inner balance.

The reactive phase may provide members powerful therapeutic benefits. For many, the phase provides an important space where they may more freely express aggression and anger and learn that such expressions are not inevitably met with retaliation but, instead, are examined for their emotional basis. Individuals emerge from this phase with a greater sense of their own authority. They experience that conflict does not lead to disaster, leaders can be challenged, and productive change may occur.

This picture of the reactive phase is incomplete because, as with adolescence, not everyone or every group rebels. Some groups progress more smoothly along the continuum of marked conflictual or quiet change.
Mature (Working) Phase
Mature phase groups can be seen as moving effectively toward their goals. Personal safety is addressed at deeper levels. Members share leadership roles; they reflect on their interactions and inner “unspoken” dialogues, thereby exposing hidden intentions and emotions. They are more collaborative with one another and with the therapist. The therapist is more readily accepted as an individual with helpful skills and abilities, but also as someone who may misunderstand or be mistaken. Tolerance for differences increases, and conflict is allowed to emerge more fully. Conflict is examined for sources rather than seen only as a disruption. Violations of norms are not automatically sanctioned but are seen as learning opportunities. Group transactions are more focused on the here and now, and exchanges are appreciated as containing reactions to the present and vestiges from prior relationships (transferences). Members attempt to understand one another at both surface and in-depth levels.

The therapist increases efforts to understand and interpret behaviors in the here and now, linking them with prior in-group experiences and with extra-group, developmental, or family of origin experiences. The therapist may take pleasure in seeing growth and sharing leadership.

In this phase, members can more flexibly assume multiple roles. They see others as separate individuals with their own wishes, desires, strengths, and difficulties.

Termination Phase
When groups prepare to terminate, members respond to the impending loss in a fashion similar to stages of grief: denial, anger, bargaining, depression, and acceptance (Kubler-Ross 1967). At first, there is disbelief that the group will end, and discussion of the ending date is quickly squashed. Some members, in the service of denial, will talk about all the things they can do when they are relieved of regular attendance. Anger is voiced at not having achieved idealized treatment goals and is fueled as protest against the loss of real relationships with peers and the therapist. Commonly, patients try to bargain for extensions, or they discuss the possibility of finding another therapist or meet another therapist on their own. As the reality of the ending comes closer, evidence of depression appears. Finally, acceptance appears mixed with appreciation for the gains that have been made and the recognition of the undone work. The future is explored with a mixture of apprehension and anticipation of trying out one’s new experiences as a more integrated and flexible person.

Members revisit previously examined behaviors and inner conflicts—these regressive features are not identical to what had been exhibited earlier, because of learning during the treatment. Dependency strivings, idealizations, or anger in response to powerlessness (to alter the ending) reappear. These regressive experiences provide the members additional opportunities to examine problems and reinforce gains. Characteristic of the termination phase, these periods are of briefer duration and lessened intensity.

Summary
Groups do not uniformly traverse developmental phases. They will shift to earlier stages in response to various stresses, such as vacations or change in membership. Considerable therapeutic work takes place at each developmental level. A group of individuals experiencing problems with basic trust may require considerable time in an initial stage, for the members to become familiar with and to gain mastery over their basic sense of distrust. The group work could be considered a success with that achievement. Patients who need to address competitive feelings need to work at more advanced stages. Understanding group development provides a framework for therapists to appreciate the forces that impact on members’ feelings and behavior.

Therapeutic Factors
In dynamic therapies, specific and nonspecific elements contribute to therapeutic change. In groups, the presence of others adds to factors present in all dyadic healing relationships (Yalom and Leszcz 2005). Nonspecific factors are embedded in the relationships established through a consistent, accepting, nonjudgmental, and supportive environment. These are all elements of a cohesive group. Groups provide a corrective emotional experience in which patients experience others (including the therapist) responding to them differently than those in their past. Members share their stories (catharsis) and feel less isolated when others have shared similar stories (universalization); they have opportunities to be helpful to others through both cognitive understanding and emotional linking (imparting information, providing feedback, and altruism). They also see others improve, which conveys hope. These elements contribute to the sense of collaboration and a willingness to adopt norms (i.e., discuss feelings about the interactions in the meeting) that further members’ sense of efficacy and belonging. Taken together, these nonspecific elements add to group cohesion, which has been likened to the therapeutic alliance in dyadic treatment. They contribute to an experience of support and acceptance, which may be sufficient therapeutic gain for a number of patients.

Additional nonspecific elements that contribute to change are opportunities for imitative learning. Patients observe and imitate others’ successful interactions. Members may model and practice new ways of interacting in the protected setting of the group and thereby disaffirm prior beliefs that their behaviors will elicit noxious responses.

Each theoretical school emphasizes its own specific contributions to therapeutic change. The interpersonal tradition privileges giving and receiving feedback about behaviors in the here and now as central therapeutic factors. Other psychodynamic theorists emphasize resolution of transfers, resistances, or unblocking developmental arrests. The group is conceptualized as re-creating the family of origin or as a microcosm where enactments of previous experiences with parents or siblings or other important relationships will emerge. These then become available for modification through the relational experiences and interpretation.

Within the psychodynamic tradition, change mechanisms of confrontation, clarification, and interpretation promote imitation and identification, optimally leading to internalization and change in psychic organization (Rutan et al. 2007). Members and therapist contribute to these processes, albeit in an unequal manner. Indeed, an asset of group treatment is that participants learn to appreciate less than conscious motivations in themselves and in others and develop a capacity to empathize with others in the immediacy of the group setting. Moreover, they can experiment with novel ways of behaving. Individuals successfully completing group treatment cite the help of member-to-member...
The Practice of Group Therapy

Organization a Group

Forming a psychodynamic therapy group is complex, and attention to organizational details will anticipate hazards and smooth the path to success. Composition, size, fees, place, duration, and time of meetings are elements that require decisions in advance of recruiting and preparing potential members.

The size of dynamically oriented groups ranges from six to 10 members. Groups at the upper size range generally meet for lengthier periods to provide sufficient time to participate for each person. Smaller groups (four members or less) may be threatened by fears of dissolution. The duration of meetings generally ranges from 75 to 120 minutes, the norm being 90 minutes. Groups meet once or twice weekly. Physical arrangements require attention, including place for members to gather before the meeting begins: an unobstructed treatment room allowing members comfortable, but not necessarily identical, seats.

The therapist should make advance decisions regarding the day and time of the meeting. Most outpatient adult groups meet in the evening, maximizing opportunities to recruit members. Initially, the group time can be used to interview candidates, thereby clarifying the patient’s ability to attend. Attempts to adjust time or day to accommodate interview candidates, thereby clarifying the patient’s ability to attend. Attempts to adjust time or day to accommodate one or two prospects are generally inadvisable.

Most therapists prefer to establish a uniform group fee. Nevertheless, managed care stipulates charges and does not permit “balance billing,” thereby limiting this policy. Policies about charges for missed appointments should be decided in advance. Whatever the ultimate arrangements, as set in the agreement (discussed later), therapists have the task of helping patients be responsible for their fees.

Careful thought must be given to optimal group composition (Table 90–3).

Patients chosen for groups that will explore intrapsychic and relational difficulties should have a capacity for self-reflection and empathy. If possible, members with different personality styles should be selected to provide a spectrum of interactive patterns. Other long-term groups may be established with supportive goals and include patients with significant ego deficits. Groups designed with a specialized format (e.g., survivors of sexual abuse or other traumas, male perpetrators, or individuals with eating disorders) generally are more focused on a symptom, a specific experience, or behavior, and in such cases balanced membership is of lesser importance.

The task of composition is not to exclude differences but to create a group where the differences are not so great that emotional links cannot be achieved. Groups can be started with unequal numbers of men or women, but open places should be used to equalize membership. If possible, at least two members of each gender should be included to reduce stereotyping and isolation and to promote identifications. Age ranges might be limited in groups composed of late teenagers, young adults, or elderly persons; however, in groups whose members have attained their late 20s, the range may be quite broad.

Recruiting, Selecting, and Preparing Patients

Few applicants requesting psychotherapy consider group treatment. Thus, gathering 6–10 individuals together may not be a simple task. The optimal place to recruit patients is from the therapist’s own individual practice. These individuals have a relationship with the therapist and can more readily collaborate in a decision to join a group. Colleagues are helpful referral sources, but the therapist must provide the necessary information regarding the group’s goal and patient characteristics to facilitate referrals. In clinic settings, admission staff are in a particularly helpful position to assist recruiting members.

Patients are more likely to agree to enter a group if they are provided a detailed rationale for the treatment format. The therapist needs clarity about the relationship between group goals and patient goals (to be discussed below). In interviewing prospective members, the therapist should become familiar with the patient’s history, coping style, symptoms, and personality configurations. In obtaining a patient’s developmental history, the therapist can specifically search for the person’s interaction in group settings, such as school, church, recreation, and family. Discussion of the person’s typical reactions to group situations helps engage the patient in examining his/her response to interpersonal situations. An important element in informing patients about group treatment is the clear boundary between what is introduced in the group and dyadic settings (either the preparatory interviews or the individual treatment sessions). The patients are responsible for bringing information from those interviews to the group. The therapist will respect the patient’s privacy and autonomy. The screening and preparatory interviews have five major tasks (Rutan et al. 2007):

1. Establish a preliminary alliance between patient and therapist.
2. Define the patients’ therapeutic goals.
4. Explore the patients’ anticipatory anxiety.
5. Discuss the group agreement and gain the patient’s acceptance.

Several individual interviews may be necessary to determine applicants’ suitability for the group. Before joining a group, some individuals then benefit from or choose to work on understanding their feelings more thoroughly in dyadic treatment.

For those who seem suitable, preparatory interviews help them anticipate their emotions about joining and form a beginning alliance with the therapist. Careful preparation will decrease but not eliminate premature termination.

Patients may be informed that a group goal is establishing free-flowing interaction and discussion where members may experience and learn about problematic aspects of their inner and relational worlds. Individual goals may be formulated in both interpersonal and intrapsychic terms. For example, a patient who wishes to address his/her difficulty in sustaining intimate relationships may use the group to examine his/her feelings, in order to determine which interactions stimulate or diminish his/her desires for intimacy. The goal would be to learn about both the current (in-group) stimuli and the past experiences that evoke these emotions and responses. Inquiry into a patient’s recent dreams, either in anticipation of preparatory sessions or between screening interviews, will expose less conscious aspects of anticipatory anxieties. The patient can also be told that he/she might discover previously unrecognized problems that he/she wishes to pursue in his/her group treatment.

Therapists often are discouraged or frustrated by the difficulties they encounter in gathering sufficient members to begin group treatment. Clinicians unable to recruit prospects from their own practice may have hidden resistance to group treatment. Consultation is useful in providing support and may expose countertransference responses to prospects or uncover resistance to assuming the leadership tasks (Billow 2001).

The Group Agreement

The group agreement represents the framework in which treatment will proceed. It promotes a structure that defines boundaries between the group and the environment, among the members and with the therapist. Although members accept the agreement, they also disregard it. Such behaviors provide valuable opportunities for understanding a person’s inner world. The therapist must distinguish between acts that are disruptive to the group and those that carry more benign communications (Nitsun 1996).

Rutan et al. (2007) list the elements of the agreement as shown in Table 90–4.

<table>
<thead>
<tr>
<th>Table 90–4 The Group Agreement</th>

</tr>
<tr>
<td>Be responsible for fees</td>
</tr>
<tr>
<td>Understand the therapist’s role</td>
</tr>
<tr>
<td>Protect the confidentiality of the meetings and the anonymity of members</td>
</tr>
</tbody>
</table>

Inevitably, members will have contact with one another outside the sessions. Contact may be limited to brief encounters immediately before or after the meeting, or eating together after a session. On occasion, patients develop substantial relationships with one another. The therapeutic aim is to create an environment in which these contacts can be discussed and their meaning addressed. Rarely do these extra-group meetings lead to sexual liaisons, which may be destructive to treatment. With patients understanding that continuing such liaisons will interfere with their remaining in the group, most will discontinue their sexual relationships. The greatest danger to the group exists in silence surrounding outside contacts.

Members may be asked to file insurance forms and to be responsible for their fees and copayments. If payments are not made within the agreed time frame, the failure should be openly raised within the group. Money often assumes major importance in patients’ lives, with linkages to self-esteem, shame, competition, and power. The therapist “swims upstream” when he/she introduces problems with fees in the group, but failure to do so excludes from therapeutic scrutiny important aspects of patients’ inner experiences.

As part of the agreement, therapists include a description of their role. They may merely indicate that they will try to help members understand themselves and others. They should describe how they will inform the members in advance.
when they are to be absent or will make arrangements in case of emergency. When insurance requires disclosures in order to continue providing benefits, the therapist needs to inform the patient of what information (including diagnoses) will be disclosed.

Discussion of confidentiality is left to last in order to emphasize its importance. No guarantee can be made about member confidentiality, but stressing the significance of maintaining others’ anonymity if material from the group is discussed is easily understood and does not interfere with members’ freedom to process their treatment experience with persons outside the group.

The agreement creates a structure within which the therapeutic work can proceed. However, it leaves room for considerable ambiguity, which can be used for therapeutic discussion. The agreement is presented to prospective members before joining and should be repeated at the time of the initial group session when new members are added and subsequently woven through the treatment process.

**Therapist’s Role**

The group leader assumes a major, but not the sole, responsibility for the treatment. The therapist’s special role is established in part by the agreement. Within that framework, clinicians begin to shape the group to provide participants a way of using their experience to learn about themselves. Assuming that patients’ optimal learning emerges from a focus on within-group transactions, psychodynamically oriented therapists try to find ways of helping members examine resistances and defenses against such engagement. In contrast, clinicians using a more strictly interpersonal (Yalom and Leszcz 2005) or a system-centered orientation (Agazarian 1997) may actively instruct members to address one another directly in the here and now. The therapist’s interventions contribute to bonding to himself/herself and with one another, thereby furthering cohesion (Billow 2003b). The goals of the different approaches are similar—to use the intragroup processes to promote personal change. Whatever perspective therapists take, they should attend to their own contributions to the group dialogue.

The therapist’s focus, however, is not exclusively on in-group processes. Rutan et al. (2007) list six foci for the therapist’s attention (Table 90–5):

<table>

</table>

The major but not exclusive focus promoting change is members learning from the here and now of treatment. Groups develop a rhythm in which members might address outside events as a warm-up to exploring in-group interactions, or they might focus on current feelings and then expand on those experiences in respect to their outside lives, in the present, past, or future. Integration of a person’s experiences across an extended period enhances feelings of continuity and stability of the self.

In a similar fashion, to-and-fro movement takes place in the therapist’s focus from group as a whole, to subgroups to interpersonal to individual. Whole-group processes seldom completely disappear. Group-as-a-whole interventions tend to address individuals earlier developmental levels than do more interpersonal or intrapsychic interventions (Kernberg 1975). Premature group-as-a-whole interventions may be experienced as insensitive and injurious. Horwitz (1977) proposed that therapists identify a group theme and explore individual experiences linked to the theme before making a whole-group interpretation. (Recent contributions to group as a whole perspective are provided by Kibel 2005, Agazarian and Gantt 2005, and Stone 2005). No matter the level therapists choose to intervene, all levels of the group will be affected by the therapist’s activities.

The therapist monitors the ebb and flow of affects. Members’ capacity to tolerate intense feelings is enhanced as trust and cohesion increase. A dialectical tension between affect and cognition is seen in members’ roles, as they attempt to contain dysphoric states and sustain emotional contacts with one another. Some individuals require cognitive understanding before risking immersion into feelings, whereas others search for affective connections before integrating their experience cognitively.

The therapeutic process is partly fueled by members’ repeating of old conflicts and defenses and partly by searching for new solutions to their developmental arrests and conflicts (Stone 2003). Members may unconsciously communicate feelings about their in-group experience through associations to events in their outside world. As such, the associations can be understood as metaphorical communication that informs the treatment process. After a successful interpretation or clarification, associations to external or historical events may represent integration of those experiences into members’ psychic structure.

Considerable individual change takes place via the group relationship without overt cognitive integration. The sense of sharing, of being understood, of having needs met, and of being responded to in an empathic manner may stabilize a shaky psychic structure, and, some patients, to their therapist’s surprise, may successfully terminate treatment without having achieved understanding (Rutan et al. 2007). These are the powerful forces for change, labeled “corrective emotional experiences.” Patients also strive for cognitive integration of their thoughts and feelings, and, through experiencing and then understanding the here-and-now, external, and developmental incidents, they consolidate their learning. Patients are then more prepared to transfer their learning from therapy to situations in their outside world.

**Initiating Treatment**

Beginning a group is suffused with anxiety for all involved. Therapists worry, “Will anyone come? Will the members get along? Will they learn to work together? Will affects get out of control?” Patients have similar concerns, and they face the additional tasks of figuring out how to meet strangers and how to use the group to achieve their therapeutic goals.

The therapist provides the initial structure, which can be accomplished by reviewing the agreement and asking individuals to introduce themselves. Following these
the impact of these events on the remaining group, as well as find replacements (Roback and Smith 1987). Repeated dropouts may lead to demoralization among the members.

Despite the stress, the majority of members derive benefit from this treatment phase by sharing problems and experiencing diminished isolation and shame about psychological problems. Not surprisingly, many individuals report feeling better, and, as a consequence of their membership, they may experience a disappearance of somatic or emotional symptoms.

**Treatment Course**

Members’ level of self and ego development influence the course of the group as a therapeutic agent. Persons suffering from archaic conflicts of trust or psychic safety, as expressed in a variety of personality disorders (the difficult patient), may require an extended period of therapy exploring these issues. Transferences to the group, leader, or peers emerge, which reflect these developmental levels. The group may be experienced as an archaic maternal image: warm and protective or hostile and destructive (Scheidlinger 1974). The therapist may be cast in a similar light or splits may occur in which the therapist is experienced as the bad parent and the group as the good parent. Interactions may be conceptualized in the paradigm of self-psychology, with the therapist being experienced as an idealized self-object.

For some individuals, achieving a treatment alliance in which others are experienced as separate and unique may be a sufficient treatment goal. Stabilizing the self, as a result of feeling understood or accepted, may be sufficient for some patients who may terminate treatment, often to the surprise of the therapist (Stone 1985).

Patients gradually learn to address their in-group transactions. Use of tension-deflecting mechanisms diminishes or is more quickly recognized (e.g., scapegoating, invoking humor, or externalizing), and members assume leadership in redirecting derailed conversations. Members develop a useful group memory and linkages between current interactions and past meetings as part of the working-through process. Triangular themes emerge, and patients examine competitive strivings and their envy, jealousy, guilt, and shame (Alonso and Rutan 1988). Their sense of efficacy is enhanced as they experience themselves capable of becoming truly empathic and contributing to group work.

Individual termination represents an important emotional phase in treatment. Until a person successfully terminates therapy, groups do not reach their full potential. The therapist may be aware of patients’ readiness to terminate treatment before a member will directly address leaving. Some therapists ask members to remain for a specified number of sessions after announcing a decision to leave. Members generally resist fully facing the feelings associated with saying goodbye. Some persons abruptly announce that they are leaving in the following one or two sessions, an all too brief goodbye. Optimally, members will discuss their thoughts about terminating over the course of a number of sessions before making a final decision. Then a future date should be set.

Terminations often stimulate regression that enables the departing person to gain additional self-knowledge. Other members become embroiled in feelings of saying goodbye, becoming critical of the decision or searching for
defects in the departing member that would contraindicate termination. Envious or shameful emotions fuel these interactions. The therapist must carefully assess the situation and may need to “protect” the person’s decision to leave. Affect contagion from members’ anxieties over loss may spread to the leader and interfere with his/her judgment. Moreover, therapists may experience countertransferences over losing a member who significantly contributed to the process (Karterud and Stone 2003). Patients may wish to celebrate departures with a party or exchange of gifts. Careful discussion may help determine the value or the defensiveness of such rituals (Shapiro and Ginzberg 2002). In most instances, the patient’s final session is filled with considerable sadness as well as pleasure.

**Special Treatment Considerations**

**Dreams**

Many therapists encourage members to present dreams by including in the agreement that dreams may be helpful in understanding not only the individual but also aspects of the group itself. Some dreams directly portray members and/or the therapist, whereas others may dramatize emotionally laden collective situations, seemingly unrelated to the group experience (Stone and Karterud 2006).

The dreamer should be provided an initial opportunity to examine the dream. The therapist may inquire if others have responses and, after their associations are made, may ask about feelings or unexplored dream elements. An important clue to the meaning of the dream may be in the interactions that immediately precede the dreamer’s report or in the associations following inquiry of the dreamer and other members. Complete analysis of dreams is infrequent. Dream work may help surface many unexpressed conscious feelings, expose unconscious conflicts, and facilitate more direct interaction.

**Scapegoating**

Group psychotherapy has been called a hall of mirrors (Foulkes 1961), where aspects of oneself are seen reflected in others. Scapegoating is the process in which individuals, by “observing” characteristics in another that are unacceptable in themselves, try to deny their feelings and place them solely in the “offending” person. This process, involving projective identification, is frequently activated during treatment and is by no means entirely conscious (Cohen and Schermer 2002).

Many affects, such as anger, envy, or romantic feelings, may serve as stimuli evoking scapegoating. If the affective intensity is magnified, through emotional contagion or personal vulnerability, and the scapegoat is isolated or extruded, the group is depleted because these affects become walled off and unavailable for examination.

The therapist protects the scapegoat and helps members expand their emotions through assisting them in “taking back” feelings attributed solely to the scapegoat. A simple illustration is members’ anger with an individual who habitually arrives late. That person might be accused of wanting to avoid the group. Analysis of the members’ vitriol may reveal that they are avoiding their own wishes to distance from the group. Such an analysis links the scapegoat to others and decreases an isolating experience.

**Nonverbal Communication**

Patients communicate powerful feelings nonverbally. Discrepancy between verbal and nonverbal messages is confusing, but frequently the latter is perceived as the “truth.” Patients may tell sad stories and laugh, or they may relate a success in a dreary manner. Seating arrangements may reflect important emotions. Members may pull their chairs outside the group circle, sit close to or opposite the therapist, shift position in their chair, or not look at one another during emotionally laden interactions. White knuckles, crimson blushing, or a black dress are additional colorful communications.

Patients learn to address these behaviors as meaningful communications. However, many times the person may be unaware of sending nonverbal messages, and confrontations can be experienced as intrusive and threatening. Stereotyping certain behaviors as carrying predetermined meanings is a common error, and patients learn, sometimes through painful experience, that the sender may have highly personal meanings attached to the behavior. Exploration of nonverbal behaviors often is a powerful entry into the recipient’s and the sender’s current and past emotions.

**Difficult Groups and Patients**

All clinicians, regardless of experience, find their groups difficult some of the time. Therapists may feel incompetent when they are destabilized by the group process, content, or emotions. Inexperienced clinicians have greater difficulty regaining their equilibrium and may feel unable to do so (Rutan et al. 2007). Such difficulties may arise from the selection and mix of patients, which interfere with the group making progress in accord with the clinician’s therapeutic ambitions.

A number of individuals who appear to be good group candidates subsequently prove to benefit little from participation or obstruct the treatment process. These individuals, generically labeled “difficult patients,” can be conceptualized as having significant relational problems that interact with a particular group culture (Roth et al. 1990). Although such individuals are often diagnosed as having borderline or narcissistic personality disorder, not all difficult patients can readily be given those specific diagnoses. Nitsun’s (1996) felicitous expression, “the antigroup,” characterizes these individuals as having the potential to disrupt the entire therapeutic endeavor.

The difficult patient should be seen in context. Some groups can accept individuals who seldom speak, whereas others see such a person as seriously harming cohesion and, therefore, as “difficult.” Difficult patients fill roles and are frequently labeled “monopolizer,” “help-rejecting complain,” or “the silent one.” The role embodies both the individual personality and the group function. Evidence for this assertion is found when the difficult individual is removed and another rises to fill his or her place, which suggests that, in part, the role was necessary to deal with members’ anxieties.

A careful examination of the processes involved in the emergence of a difficult patient may expose that such individuals are covertly coconstructed by others in the group (Gans and Alonso 1998). Interactions among members and the therapist tend to evoke and/or exaggerate particular character tendencies of members who often have underlying
issues of forming intimate relationships. The therapeutic challenge is to deconstruct the processes so that all can see their contributions to the difficult individual.

Nevertheless, some patients persist in behaviors that do not change or become destructive to the treatment process. They evoke responses in others, including the therapist, that interfere with a sense of safety, limiting members’ willingness to expose their inner thoughts and feelings (Stone 2001). Many difficult patients seem unable to process their interactions cognitively but remain enmeshed in emotional exchange. Others may interrupt emotional exchange with intellectual dissertations.

Not infrequently, these individuals prematurely terminate treatment, leaving those remaining with feelings of relief, frustration, and anger. Other difficult patients remain in the group, and at times the therapist is faced with making a decision that favors the group over an individual. The patient is informed that she or he is not benefiting from the treatment modality and is asked to leave. Such a decision should be reached only after the therapist has completed a thorough self-scrutiny and has sought consultation to explore countertransference contributions to the impasse.

Alternative Treatment Formats

Cotherapy

A cotherapy format provides opportunities for clinicians to learn from one another, share leadership responsibilities, increase member recruitment, and provide continuity in the absence of one leader. Therapists can directly observe another clinician’s work and learn about countertransferences. In the treatment process, when one therapist is engaged in a particularly stressful interaction, the second clinician can have sufficient distance to help understand the situation. The model is most often utilized for training neophyte therapists who can be paired with a more experienced therapist. For patients, this model is thought to offer a recreation of the family, as therapists are cast in parental roles, whether or not the therapists are of the same or different gender.

The conduct of cotherapy is not without difficulties (Lang and Halperin 1989). Cotherapists are susceptible to a variety of transference responses to one another, most commonly competitive and narcissistic strivings. These emotions may be artfully stimulated by the members. Therapists should routinely schedule time to review their emotional responses to one another and to the members, in order to keep their relationship on course and enhance their therapeutic efficacy.

For patients, cotherapy offers opportunities to observe two individuals working together and observe how their relational problems are addressed. In their transference or realistic responses, they may assign roles or split cotherapists into good and bad. These responses may either derail treatment or provide new opportunities for therapeutic growth. Consultation is advisable when therapists seem to reach an impasse in resolving conflicts or the group seems stuck.

Determining fees for cotherapy sessions is complex. Some therapists set a fee for the session that remains the same with one or both therapists present. This is compatible with insurance policies of paying for a service. Some therapists charge individually and only when they are present. Therapists should be prepared to explain their policy but also to examine responses to whichever policy they choose. Money is a difficult topic in our culture and often evokes countertransferences.

Concurrent Therapy

The practice of combining individual and group psychotherapy has gained considerable acceptance. Patients may be seen either by the same (combined) or by a second (conjoint) therapist. Each modality potentially complements the other. In dyadic settings, therapists can focus in greater detail and more readily explore developmental (transference) contributors to group transactions. Similarly, material brought into focus in the dyadic setting can be explored as it is displayed in the group.

In the combined model, therapists have opportunities to observe individuals in both settings. Most therapists draw a clear boundary between the two modalities—that is, they will not introduce information into the group that was learned elsewhere; the patient is encouraged to assume that responsibility (Lipsius 1991).

In the concurrent model, the majority of therapists obtain the patient’s consent to communicate about the treatments. For some, absence of consent rules out this treatment arrangement. Therapists, by exchanging information, inform one another to the emerging transferences. The format may stimulate splitting, in which a patient may denigrate one treatment and idealize the other. Through consultation with one another, therapists can sort out precipitants for those behaviors and diminish the potential for countertransference responses and unproductive treatment experiences.

Not uncommonly, some group members may be treated in concurrent formats, whereas others are not. These arrangements stimulate direct questions or allusions to specialness, favoritism, and degree of illness that require exploration, e.g., persons in concurrent treatment may be viewed as sicker, or getting special attention. Generally, the patient may be the one to initially reveal his/her individual sessions to the group. The timing of such references often carries considerable meaning that can be examined therapeutically.

Pharmacotherapy and Group Therapy

Combing pharmacotherapy with dynamic group psychotherapy is widely practiced. Inclusion of medicated individuals broadens the population available for treatment. Medications are often seen as helping patients focus effectively and thereby make greater therapeutic gains. Arguments against combining psychotropic medication with group therapy include therapists’ belief that medication interferes with patients’ personal ownership over themselves. Nonmedical therapists may be adverse to introducing medicated patients to their group because of problems in collaboration with physicians.

A common dynamic process is exposure of attitudes derogating medicated members and a “we–they” split, which may result in medicated patients becoming scapegoated as “too ill”. Focusing on medication may become a group resistance. Discussion of treatments of other medical illnesses that involve medications (diabetes, hypertension, and arthritis) may also contain displaced emotions regarding psychotropic drugs.
Time-Limited Groups
As pressure mounts to conduct therapy more rapidly, interest in time-limited groups has increased (MacKenzie 1997). The number of sessions may range from 12 to 30. Many insurance companies limit coverage to 20 sessions, and thus a 16-session model allows for preparatory interviews and, if necessary, one or two sessions after termination of the group.

Groups may be organized along specific symptom constellations, such as bereavement, sexual abuse, bulimia, or anorexia nervosa, or they may explore a personality trait (assertiveness and anger control) with the expectation that the individual will continue to utilize the learning after termination. Therapists may opt to organize groups to provide support (e.g., during a crisis) or with patients able to work in an interpretive mode. Applicants should be assessed for capacity to reflect on themselves and their interactions, and on their ability to find a focus for their work. Difficulties should be formulated in interpersonal terms to facilitate the exploration of the problems in the group setting (e.g., a delayed grief reaction, Piper et al. 2001).

In most models, once treatment begins, additional members are not accepted to the group. The agreement is similar to that of longer-term groups, with the exception that the number of sessions is limited. Using this format, the therapist needs to be more active in defining the focus for the members and attending to the therapeutic alliance. Interventions are most effective that focus on interpersonal exchange, which also reflects the stage of group development. Time-limited groups can be particularly useful in addressing issues of engagement, trust, unfulfilled hopes, separation, and loss. The combination of time pressure, maintaining focus on interpersonal processes, and providing encouragement to apply learning in the external world has produced a treatment format that may be as effective as individual treatment (Budman et al. 1988).

Cognitive-Behavioral Group Therapy
Cognitive-behavioral group therapy (CBGT) is an adaptation of the dyadic treatment format to the group setting. One of the cornerstones of the cognitive-behavioral therapy (CBT) approach is the concept that one’s thoughts, beliefs, and assumptions (i.e., interpretations) of events can lead to overly negative (or unrealistic) thoughts. The purpose of cognitive restructuring is to identify less negative (or more realistic) thoughts, which will then expand options available to the individual and alter depressive and anxious feelings. This evidence-based treatment has been applied to a broad spectrum of disorders and patient populations (White and Freeman 2000, Bieling et al. 2006). Suls et al. (2000) list 10 common CBT methods that are utilized both in individual and in group settings:

1. recording of automatic thoughts;
2. challenging the thoughts—what is the evidence, what are alternative interpretations;
3. mood monitoring—use of checklists;
4. developing hierarchy of arousal—stimuli cause anxiety;
5. active monitoring—keep records during the day;
6. problem solving—no single answer, multiple solutions;
7. relaxation strategies;
8. risk assessment—counters “catastrophizing”;
9. treatment protocols—embedded within a therapeutic relationship;
10. relapse prevention—learn to identify and deal with triggers.

Patients are offered a description of the therapeutic value of group participation. Groups are generally time limited (10–sessions), and the therapeutic value of group treatment is outlined, which would include vicarious learning, universalization, altruism, hope, and a public commitment to change (Heimberg and Becker 2002).

Individual interviews are employed to assess and prepare applicants for group treatment. During these interviews, patients are introduced to the principles of CBT. Included in the general criteria for participation in a group are patients’ abilities to help others and a commitment to change. Exclusion criteria are similar to those of psychodynamic groups, including persons whose fear of groups was too great, active use of illegal substances, or acute situational disorders. Patients using anxiolytic or antidepressant medications may be included, often with the goal of discontinuing these medications as symptoms improve. Group size is from four to six. Sessions typically range from 120 to 150 minutes. Groups are led singly or with cotherapists.

The group sessions are semistructured; usually the first session orient patients to the procedures, the middle sessions are used to work on the problems, and the final session focuses on change during the treatment, consolidation of learning, and anticipation of the future, with attention to relapse prevention. In the orientation session, therapists provide an overview of the therapeutic procedures, generally including a member’s check-in and report of homework, developing an agenda or topic, working on members’ experiences or thoughts related to the topic, determining homework for the next sessions, and completing weekly outcome measures. In the middle phase, sessions are devoted to exploring members’ hierarchy of automatic thoughts and core beliefs. For anxiety disorders (social anxiety, phobias, or panic disorder), the hierarchy consists of the feared situations, and they are addressed in the group and in the members’ lives as part of the homework. In some approaches, the therapist lists members’ suggestions for topics or issues on a chalkboard, and members vote on which topic will be addressed. In other models, the members take turns in introducing the topic for discussion. In the final phase, members are asked to review their progress, consolidate their learning, and attend to triggers that may lead to recrudescence of symptoms.

During the middle phase, considerable emphasis is placed on cognitive restructuring. At the beginning of each session, homework is reviewed. Failures to complete homework are viewed as opportunities to explore automatic thoughts that have interfered with completion of the task. The topic of the session is established. Fearful situations may be role played or may be imagined, and automatic thoughts challenged, looking for evidence for or against the feared outcomes. The therapist monitors members’ level of arousal, or tension, and assesses progress in the direction of mastery and pleasure. The therapist may ask Socratic-type questions eliciting alternative adaptive responses. Members are taught not to give advice and that no single solution is “correct.” Members are engaged in considering adaptive alternatives to their habitually feared outcomes. In some groups,
relaxation exercises and meditation are included as additional adaptive strategies.

Group dynamics are activated by empowering the participants, diminishing dependency, and promoting cohesion. Members have opportunities to see how they are faring by reviewing the status/outcome measures, thereby providing evidence for their state of progress. These models emphasize problem solving (adaptive responses) and minimize exploration of intragroup conflict. Norms develop that help members assist one another in facing feared situations or conflicts, which then enhance self-efficacy.

Some models limit treatment to a single series of sessions. Others have follow-up sessions, which serve to reinforce learning or then move to individual treatment to explore difficulties in further depth. Outcome is measurable, and patients can see for themselves what they have achieved.

**Persons with Persistent and Severe Mental Illness**

This special population of patients requires modification of traditional dynamic approaches (Kanas 1996, Stone 1996, Schermer and Pines 1999). The population is broader than individuals with major psychiatric disorders (schizophrenia or bipolar disorders) and includes some disabling anxiety or personality disorders. Indeed, chronicity is determined primarily by duration and disability rather than by diagnosis. In some instances, groups are organized homogeneously for patients with schizophrenia or bipolar disorder. These groups often emphasize the importance of continuing with medication and include significant educational components. They may have greater structure and focus on particular topics, such as managing hallucinations, paranoid thinking, or social relations (Stone 1996).

More typically, groups are structured to include a spectrum of patients within a relatively small range of impairment. Patients are prone to attend erratically, and a flexible format that accepts this propensity may serve these individuals well (Stone 1996). The sessions last 45–75 minutes, and the group census may range from 12 to 16 persons. In the flexible format, core and peripheral subgroups develop, and, over extended periods, groups develop a sense of continuity and cohesion.

Treatment goals should be concordant with patients’ strengths and are generally formulated to help adapting to everyday problems, improving social relations, and managing feelings. The agreement is modified, and patients may be encouraged to socialize outside of the meetings. Therapists attempt to help patients manage their isolation and sense of shame over their illness.

Countertransferences require particular attention in part due to the difficulty patients have in linking to their therapists, which may leave the clinician expecting more than the patients can deliver. Moreover, in the current climate, particularly for major mental illness, medications are valorized, and therapy is depreciated, a state of affairs that affects the therapist.

**SH Groups**

The SH group movement, emerging from Alcoholics Anonymous, is a massive, varied, and not fully delimited social phenomenon. It has been estimated that upward of 12–14 million people participate. SH groups are widely available for almost every illness, experience, or social problem. Groups are advertised in local newspapers for widely varied conditions, including bereaved parents, siblings of children with special needs, and multiple sclerosis patients. SH groups can be conceptualized with an overarching perspective that “all are collections of fellow sufferers in high states of personal need and that all require some aspect of the personal and often painful affliction to be shared in public” (Lieberman 1993, p. 293). Groups are held face to face and more recently through the Internet. Common characteristics of the SH group include: (1) a similar presenting problem, an illness, status, or problem. (2) expectation of reciprocal help among the members. (3) indigenous leadership. (4) no fees, minimal charges, or voluntary contributions (Goodman and Jacobs 1994). Common goals include mutual support, normalization of condition or social situation, sharing of information, developing coping skills, and reality testing.

SH groups are not defined as therapy; participants do not define themselves as patients or clients. They have emerged for many as an alternative or a supplement to medical care or social or emotional needs.

SH groups develop their own structures and norms, with considerable variation in frequency, duration, and membership. Leadership is generally provided by indigenous members. Members, thereby, are both providers and consumers (Yalom and Leszcz 2005). Professional leadership is uncommon, but professionals may be involved through referrals, as consultants to the process or for information, or members.

Mutual sharing is the bedrock of the SH group. Therapeutic factors include catharsis, universalization, altruism, cohesion, gaining information, imitative behavior, and hope. The group process is characterized by greater emphasis on listening and acceptance, with less questioning, with acceptance of others illness or emotional state. Responses often reflect similarity of the difficulties, which increases cohesion and potentiates further self-revelation of members’ shameful or guilty secrets. Conflict and working with relationships within the group are generally eschewed. Conflict may be addressed through generalizations and suggestions for alternatives to anger. Relief or change of the participants does not follow a planned, structured, or initiated intervention according to any theoretical approach.

SH groups have emerged in the Internet and expanded opportunities for participation to individuals who are unable to physically belong, either through distance or through infirmity. The PEW survey estimated that 15,000,000 visited an online group during 2003 (Pew Internet & American Life Project 2003). They may be professionally led and held at specified times or, similar to chat rooms, may be available 24/7. Internet groups have the potential for greater anonymity, which may provide safety and more selective participation. Drawbacks include lack of personal information, the potential for disseminating, uncontrolled exchange of angry feelings, crude aggression, or only selective reading of postings. The effectiveness of Internet groups may be equal to face to face groups (Lieberman and Russo 2001–2002).

SH groups fulfill an important social need. After an initial period of caution, they are generally embraced by the medical and psychological communities as a resource that can provide additional assistance that may not be available in the mainstream of care.
Individuals have been shown to benefit by combining participation in an SH group concurrently with another traditional medical treatment (Owen et al. 2004).

**Treatment Failures**

Treatment failures may be examined from an individual or group perspective. Failures may be further classified by individuals who fail to benefit and those who are harmed by the treatment.

Among those who do not benefit or may be harmed are many individuals who terminate therapy prematurely and/or abruptly. The early treatment dropout rate is substantial (Roback and Smith 1987) and can probably never be reduced to zero. Patients terminate treatment prematurely because they have been poorly prepared, have wished for supportive rather than dynamic treatment, or find themselves in a confrontational atmosphere. Occasionally, patients may be placed in a group that functions at a level substantially different from that of their own development. Patients in a sustained divergent role (monopolizer, scapegoat, help-rejecting complainer, or isolate) often invite rejection and, in that respect, repeat previously learned patterns. Some patients initially reveal themselves extensively, feel overexposed, and abruptly terminate treatment.

Other forms of treatment failure include individuals who may remain for extended periods, participating in their stereotypical patterns, without any evidence of change. Certain patients continually violate group boundaries, and their behavior seems impossible to change after examination of collective and individual factors. Extragroup socializing (which might include sexual liaisons), inability to refrain from attacking others, and schedules that preclude regular attendance are examples of situations that suggest that continued treatment might be harmful. For individuals who do not seem to change or cannot adjust to therapeutic norms, an open discussion might lead to a mutual decision to discontinue the treatment format.

Countertransference feelings may be a signal of treatment failures. Overestimation of patients’ abilities to benefit from dynamic treatment evokes frustration in the therapist, which may be communicated to a patient who then terminates treatment. Therapists who find themselves experiencing extended periods of boredom, frustration, or anger may be reflecting group-wide affects (via projective identification). The members may be attempting to communicate through this channel their experiences of being stuck or that the therapy is ineffective. Therapist’s affect can be very useful in identifying. Such co-constructed therapeutic impasses (Gans and Alonso 1998). In groups where there have been multiple treatment failures or dropouts the therapist may benefit from consultation.

**Research**

Research in treatment outcome in group therapy is considerably more complicated than dyadic treatment. Group treatment adds a large number of elements that must be taken into account. Some of these elements are the type of group (psychoeducation, cognitive, cognitive behavioral, interpersonal, supportive, or psychodynamic), duration of treatment, length and frequency of sessions, experience of the therapist (trainee or seasoned), age (children, adolescents, and adults), functional level (chronically mentally ill or “typical” outpatient), personality factors such as self-reflective capacity, and the more complex question of patient-therapist fit.

Several large meta-analyses of the effectiveness of treatment have been conducted. Toseland and Siporin (1986) reviewed 32 well-controlled experimental studies and reported that in 24 (75%) no significant differences were found in effectiveness between individual and group treatments; in the other eight (25%), group treatment was more effective. Tillitski (1990) conducted a meta-analysis of nine studies that compared group, individual, and control conditions within the same experiment. Group and individual therapies yielded similar outcomes, and the average effect size indicated that 80% of the treated patients were improved in comparison with the control group.

Lorentzen (2006), reviewing group outcome literature, concludes:

1. Group psychotherapy is better than placebo or wait-list control conditions.
2. Group psychotherapy has an equivalent effect on individual psychotherapy or other psychological treatments.
3. Therapies of different theoretical persuasions give equal results (p. 323).

He notes that these are aggregate level results and suggests that nonspecific relational factors are present in all psychotherapies. No outcome studies of long-term dynamic group treatment have been reported in over a decade.

A study of patients randomized either to time-limited individual therapy or to group therapy was reported by Budman and colleagues (1988). On multiple measures, patients in both treatments showed similar improvement and maintained these changes at a 1-year follow-up. The authors carefully reported that almost nine times (26 vs. three) the number of patients withdrew from the study after they were informed that they had been assigned to group treatment (i.e., they had time conflicts, job changes). Moreover, patients’ subjective responses indicated a strong preference for individual treatment.

Reviews of research in group psychotherapy proposed that greater attention needs to be paid to the characteristics and preparation of patients and group composition (Dies 1993, Piper 1993). The fit of patients in a particular group may well be instrumental to outcome. Patients’ coping styles may differentially interact with the type of therapy (cognitive, focused expressive, and supportive) and affect outcome. A valuable addition to the group research literature focuses on the variety of measurement systems used to assess change (Beck and Lewis 2000). Piper and colleagues (2001) investigated two patients’ personal characteristics (quality of object relations [QOR] and psychological mindedness [PM]) with either interpretive or supportive forms of time-limited short-term group therapy for patients with “complicated grief.” Patients in both therapies improved, although those with high PM did better. For grief symptoms, an interaction was found with high QOR doing better in interpretive therapy and low QOR doing better in supportive treatment.

The complexity of conducting research has limited continuing efforts to define more precisely many of the elements contributing to that success. A somewhat worrisome
tendency is for clinics under pressure from funding agencies to substitute consumer satisfaction in place of other evaluative measures. As the study of Budman and coworkers (1988) illustrated, there may be dissociation between improvement and satisfaction, particularly in short-term group.

Training
Therapists with a background in dyadic treatment do not find the shift to conducting groups simple. Adequate training is necessary to ensure that the therapist and patients alike have a satisfactory experience (Alonzo 1993).

The components of training include: (1) didactic presentations. (2) opportunities to observe groups conducted by experienced therapists. (3) participation as a member in an experiential group or as a patient in a therapy group. (4) coleadership of a group with an experienced clinician. (5) solo leadership of a group (Alonzo 1993). Supervision is essential to assist therapists in achieving increasingly sophisticated understanding of group dynamics and process, intervention options, transferences, and countertransferences. An important additional element of training in groups is exploration of ethical issues, including confidentiality, dealing with sexual contacts (between patients and those involving the therapist), dangerousness, and informed consent (Lakin 1991).

Therapists are subjected to many powerful emotional forces evoked by the group setting, and they often try to translate individual approaches to the multiperson setting, where dynamic forces have a different impact. Increased awareness of these forces is gained through participating in a group. The American Group Psychotherapy Association offers brief group experiences at their annual conference and regional societies, or independent psychotherapy training centers may provide additional opportunities to participate as a member.

The most important element in training is supervision. Beginning supervision is most often provided individually. However, many therapists continue supervision well beyond learning the basics, and they often participate in small-group supervision of their therapy endeavors. This format provides support and an opportunity for the therapist again to reexperience group dynamics in action. Often unconscious aspects of the therapist’s behavior (countertransferences) emerge in the supervisory group in a manner that can be utilized to gain greater understanding of the therapeutic process.

Many graduate-level training programs (psychiatry, psychology, social work, and nursing) provide only a modicum of training in group dynamics and therapy, and clinicians turn to other training settings, which may include a 2-year program combining the elements described earlier.

The Future
While, historically, group psychotherapy was sometimes misrepresented as a less expensive, watered-down treatment, the overall research findings and clinical impressions have helped establish it as an effective, cost-efficient, and rigorous therapeutic modality applicable to a wide variety of patient problems. It provides a more direct experience for patients working with peers, as well as with those in “authority.” The individual’s difficulties with people are not limited to the experience of a particular individual therapist but emerge in the relational context of a number of individuals, thereby broadening the entire treatment context. In this era of emphasis on cost containment and efforts to provide rapid, brief therapies, groups can provide for some a positive time-limited treatment and for others an extended opportunity to address and alter significant intrapsychic and interpersonal difficulties.

Effective group treatment, like any other therapeutic modality, depends on opportunities for training and ongoing exchange among colleagues to enhance skills and provide the best possible treatment experience for group members.

Clinical Vignette 1
In the opening minutes of a new group’s first session, a member asked the therapist how he would like to be addressed—as “doctor” or by his first name. He did not reply. Subsequent associations included several references to rudeness, followed by emergence of angry and destructive themes, quite uncharacteristic of a new group. The members appeared to have reacted to the therapist’s nonresponse as a narcissistic injury that led to displaced rage.

Clinical Vignette 2
In a session in which members had been discussing feelings of attraction to one another and consequent jealousies, Ms. K reported the following dream: Ms. L (a member) was in the corner of the room watching some little children. The therapist was having a heart attack, and she (Ms. K) ran out into the hall trying to find someone to help. Ms. K said that she had been angry with the therapist, and that is why she dreamed about the therapist having a heart attack. A member wondered what kind of help Ms. K was seeking in the dream, leading to a discussion of cardiac resuscitation, which became elaborated into ideas of mouth-to-mouth resuscitation, and then exposed sexual feelings. Ms. L’s position in the dream, her interest in playing with the children, isolated her from the competition. Prior and present competitive and romantic feelings among the members and toward the therapist emerged and were more sharply focused in the ensuing discussion. The concrete expression “heart attack” had a clear double meaning of both wishing ill on the therapist for not reciprocating Ms. K’s romantic feelings and simultaneously exposing those feelings more directly.

The cognitive and behavioral therapies have evolved as an alternative to more traditional nondirective and insight-oriented modes of psychotherapy (Beck 1991, Wolpe 1982, Kazdin 1982, Robins and Hayes 1993). The family of cognitive and behavioral therapies includes a diverse group of interventions. Nevertheless, the treatments share several pragmatic and theoretical assumptions. First, these therapies emphasize psychoeducation: patients learn about the nature of their difficulties and are provided reasons for use of particular treatment strategies. Second, the cognitive and behavioral therapies typically employ homework and self-help assignments to provide patients the opportunity to practice therapeutic methods that enhance the generalization of newly acquired skills outside of the therapy hour. Third, objective assessment of psychiatric illness is an integral part of treatment, and the selection of therapeutic strategies derives logically from such assessments. Fourth, the therapeutic methods used are structured and directive, and as such require a high level of therapist activity (often they are described in treatment manuals). Fifth, for most disorders, the cognitive and behavioral therapies are time-limited interventions. Sixth, and perhaps most important, these therapies are built on empirical evidence that validates their theoretical orientation and guides the choice of therapeutic techniques. Specifically, learning theories (i.e., classical, operant, and observational models of learning) and the principles of cognitive psychology are relied on heavily in constructing cognitive–behavioral treatment models.

Cognitive Model

The basic theories of the cognitive model are rooted in a long tradition of viewing cognitions as primary determinants of emotion and behavior. Cognitive therapy concepts have been traced as far as the writings of the Greek Stoic philosophers (Beck 1976, Ellis 1989, Dobson and Block 1988) and have been linked to a number of other influences, including the phenomenological school of philosophy, Albert Ellis’ rational emotive therapy, and the contributions of Adler and other neofreudians (Wright et al. 2003, Wright et al. 2006). However, the greatest impetus for the development of cognitively oriented therapy has been the work of Aaron T. Beck (Beck 1991, Beck 1976, Beck 1963, Beck 1964, Beck 1967, Beck 1993). For reviews of the historical bases of cognitive therapy, see Dobson and Block (1988), Clark et al. (1999), and Wright et al. (2006). Clark et al. (1999) also provide an excellent review of the philosophical and theoretical assumptions of the cognitive theory of depression.

At the time Beck began to formulate his theories, the predominant treatment approach was psychoanalytically oriented psychotherapy. Freud conceived of depression as the result of anger turned inward (Freud 1950). However, when Beck attempted to study depression from this perspective, he noted that stereotypical patterns of pessimistic and self-critical thinking and distorted information processing were essential characteristics of depression (Beck 1963). This early work led to development of a cognitive model of depression (Beck 1964), the description of specific treatment interventions, and a substantial research effort to study cognitive functioning and treatment outcome in a variety of disorders (Beck 1976, Beck et al. 1979, Beck and Rush 2000, Wright et al. 2003).

Theories given here are based largely on Beck's concepts. This model of therapy tends to give somewhat more emphasis to cognitive than behavioral factors in treatment interventions, but both are considered to be integral parts of the model (Figure 91–1).

Depending on the case formulation and the phase of therapy, attention may be directed primarily at cognitive or behavioral aspects of the disorder. In most cases, a combination of cognitive and behavioral techniques is used. For this reason, we use the term cognitive–behavioral therapy (CBT) throughout the chapter unless referring to a specific form of behavioral treatment.

Figure 91–2 displays a simplified model for understanding the relationships between environmental events, cognitions, emotion, and behavior (Wright et al. 2003, Wright 1988, Friedman and Thase 2006). This model is based on the theoretical assumption that environmental stimuli trigger cognitions associated with personal meaning that elicit subsequent physiological and affective arousal (emotions). These emotions, in turn, have a potent reciprocal effect on cognitive content and information processing, stimulating dysfunctional thoughts and worsening negative affect. Thus, the individual’s behavioral responses to stimuli and thoughts are viewed as both a product and a cause of maladaptive cognitions. In doing CBT, treatment interventions may be targeted at any or all components of the model.

Of course, many other factors are involved in psychiatric disorders, including genetic predisposition, state-dependent neurobiological changes, and various interpersonal variables. These influences are also included in the case conceptualization in CBT. Wright and Thase (1992) have outlined an expanded cognitive-biological model that can be used for synthesizing cognitive and neurobiological factors in a combined therapy approach. Contemporary psychiatric research is striving to understand how best to combine and/or sequence CBT and pharmacotherapy, and relate CBT technique to new understandings in cognitive neuroscience. Nevertheless, the working model in Figure 91–2 can be used as a practical template to guide the therapist’s case formulation and interventions.

**Automatic Thoughts and Schemas**

Dysfunctional information processing is apparent in many psychiatric disorders at two major levels of cognition—automatic thoughts and schemas (Beck 1976, Dobson and Shaw 1986, Teasdale 1983, Segal 1988, Alfrod and Correia 1994). Automatic thoughts are cognitions that stream rapidly through an individual's mind, either spontaneously or in response to some prompt or stimulus. Automatic thoughts may be triggered by affective arousal (i.e., anger, anxiety, or sadness), or conversely, affective shifts are generally accompanied by automatic negative thoughts (Teasdale 1983). Their automatic nature refers to their speed of entry into awareness and their implicit truthfulness. In this way, automatic thoughts have emotional validity (Friedman and Thase 2006). For most people, before therapy, automatic thoughts are usually not examined carefully for validity. In fact, many people susceptible to anxiety or depression often use an affectively biased manner of thinking referred to as emotional reasoning (i.e., “I feel that this is correct, therefore it is correct”). Although we all experience automatic thoughts, in depression, anxiety, and other psychiatric disorders the thoughts are distinguished by their greater intensity and frequency (LeFebvre 1981).

Beck (1967) coined the term negative cognitive triad to describe the content of automatic negative thoughts. Typically, automatic negative thoughts may be grouped by themes pertaining to (1) self, (2) world (i.e., significant others or people in general), and (3) future. As described subsequently, the themes revealed in one’s characteristic automatic negative thoughts can be used to infer deeper levels of cognition: beliefs, rules, and schemas. Once they are comfortable recognizing their automatic negative thoughts, patients can be taught to examine their beliefs and the operational rules that underlie beliefs. Although patients are not fully aware of their schemas (relatively stable cognitive patterns that are the product of ones beliefs, attitudes, and behavioral responses), these cognitions are usually accessible through the questioning techniques used in CBT (Wright et al. 2003).
Beck and coworkers (Beck et al. 1979, Beck and Emery 1985, Wright and Beck 1983) have noted that stereotypic errors in logic (termed cognitive errors or cognitive distortions) also shape the content of automatic thoughts. Examples of these processes include personalization, magnification and minimization, all-or-nothing thinking, jumping to conclusions and ignoring the evidence (e.g., disregarding the positive, or selective abstraction). Definitions of a number of common cognitive errors are included in Table 91–1. Cognitive errors help to translate between the “surface” level of cognition (revealed in automatic negative thoughts) and deeper cognitive structures such as basic assumptions, rules and schemas (Friedman and Thase 2006, Segal 1988, Young and Lindermann 1992). It has been proposed that such apparently illogical thinking during times of heightened emotion may have had evolutionary value (Friedman and Thase 2006). Specifically, cognitive distortions during periods of affective arousal tend to narrow one’s focus of attention, simplify information processing, and intensify behavioral responses. Thus, the individual may be primed to respond decisively to the crisis at hand. This is consistent with recent findings that elucidate the neurocircuitry of brain fear pathways (distinct affective and cognitive pathways). LeDoux has shown that activation of the fear pathway causes a sequential activation of affective (limbic-amygdala branch) and cognitive (hippocampal-cortical branch) pathways. However, the affective pathway is shorter and allows activation milliseconds before the cognitive pathway. This primes the system with a sequenced affective/cognitive response to fearful environmental stimuli (LeDoux 1988).

Schemas represent the sum of one’s beliefs and attitudes. They are the basic assumptions or unspoken rules that act as templates for screening and decoding information from the environment (Segal 1988, Wright and Beck 1983, Young and Lindermann 1992). Psychological wellbeing may be understood to represent the development of a set of schemas that yield realistic appraisals of self in relation to world (e.g., “I’m reasonably attractive, but looks aren’t everything.” “I can be loved under the right circumstances,” or “I must work harder to compensate for an average intellect”). Although unspoken, schemas may be inferred from one’s beliefs and attitudes. In the cognitive model, dysfunctional attitudes are the structural “bridge” between pathological schemas and automatic negative thoughts. Schemas pertaining to safety, vulnerability to threat, self-evaluation, one’s lovability, and one’s competence or self-efficacy contain the ground rules for personal behavior that are particularly relevant to the understanding of disorders such as anxiety, depression, or personality disorders (Segal 1988, Young and Lindermann 1992, Blackburn et al. 1986a, Beck et al. 1990). A number of schemas relevant to psychiatric illness are listed in Table 91–2. Bowlby has noted that most psychologically relevant schemas are developed early in life, when the individual is relatively powerless and dependent on caregivers (Bowlby 1985).

The cognitive model of psychiatric illness emphasizes the concept of stress-diathesis (Friedman and Thase 2006, Metalsky et al. 1987). From this perspective, a schema such as “I must be loved to have worth,” might remain latent until activated by a relevant life stressor (i.e., a romantic breakup). Thus, being “dumped” by a romantic partner may trigger marked emotional response in a person with a “matching” schematic vulnerability but only a normal amount of sadness in someone with a healthier schema (e.g., “The fact that she dumped me means I’m worthless” versus “I am still a worthwhile person that someone else can love”) (Hammen et al. 1989). Some schemas may be influenced by neurobiological factors. In panic disorder, exquisite sensitivity to neurobiological signals, such as the evolutionarily ancient “suffocation alarm,” may simultaneously trigger noradrenergic arousal and fearful cognitions (Klein 1993). This combination may underpin the schema “I am weak and unable to cope with distress.” In recurrent depression, neurobiological changes may exaggerate stress responsivity, undermine the individual’s hardiness in the face of adversity, and dampen hedonic capacity (Wright and Thase 1992). As a result, the individual may develop the dysfunctional attitude “I am powerless to change my destiny.”

Underlying schemas may be buttressed by either maladaptive or adaptive attitudes (e.g., “No matter how hard I try, I’m bound to fail” versus “I’m a survivor; if I just hang in there things will be okay”), but many of these cognitive structures have mixed features (Wright et al. 2003). Schemas such as “If I’m not perfect, I will fail” may lead to driven obsessional behavior, rigid attitudes and beliefs.

| Connectedness          |             |
| Emotion                |             |
| Deprivation            | The expectation that one’s needs for nurturance, empathy, or affect will never be adequately met by others |
| Abandonment-loss       | The fear that one will imminently lose significant others or be emotionally isolated forever |
| Mistrust               | The expectation that others will hurt, abuse, cheat, lie, or manipulate you |
| Social isolation/ alienation | The belief that one is isolated from the rest of the world, is different from other people, or does not belong to any group or community |

| Worthiness              |             |
| Defectiveness-          |             |
| unlovability            | The assumption that one is inwardly defective or that, if the flaw is exposed, one is fundamentally unlovable |
| Social undesirability   | The belief that one is outwardly undesirable to others (e.g., ugly, sexually undesirable, low in status, dull, or boring) |
| Incompetence-failure    | The assumption that one cannot perform competently in areas of achievement, daily responsibilities, or decision-making |
| Guilt-punishment        | The conclusion that one is morally bad or irresponsible and deserving of criticism or punishment |
| Shame-embarrassment     | Recurrent feelings of shame or self-consciousness experienced because one believes that one’s inadequacies (as reflected in the preceding maladaptation schemas of ‘worthiness’) are totally unacceptable to others |

| Limits and standards   |             |
| Unrelenting standards  | The relentless striving to meet extremely high expectation of oneself at all costs (i.e., at the expense of happiness, pleasure, health, or satisfactory relationships) |
| Entitlement            | Insistence that one should be able to do, say, or have whatever one wants immediately |

Derived from human studies of the learned helplessness paradigm, (Seligman 1975) attributional style refers to the characteristic way that people explain the causality, controllability, and impact of events. People susceptible to depression are more likely to have an attributional style in which negative events are perceived to be personally controllable (i.e., internality), far-reaching (i.e., globality), and enduring (i.e., stability) (Peterson et al. 1985, Abramson et al. 1989, Sweeney et al. 1986). There is an obvious parallel between the depressogenic attributional style of Abramson and colleagues (1978) and Beck’s negative cognitive triad.

In general, studies of people suffering from depression and anxiety have confirmed that pathological information processing is an important part of these disorders. Negative automatic thoughts and cognitive errors have been found to be more common in depressed patients than in control subjects (Dobson and Shaw 1986, Blackburn et al. 1986b, LeFebvre 1981, Watkins and Rush 1983). Similarly, automatic thoughts concerning uncontrollability, threat, or danger have been documented in patients with high levels of anxiety (Kendall and Hollon 1989, Kendall and Kendall 1987). In clinical studies, depressed subjects also demonstrated elevated levels of dysfunctional attitudes (Blackburn et al. 1986b, Simons et al. 1984, DeRubeis et al. 1990), distorted attributions to life events (Abramson et al. 1978, Peterson et al. 1985, Sweeney et al. 1986, Zautra et al. 1985, Deutscher and Cimbolic 1990), and negatively biased responses to feedback (DeMonbreun and Craighead 1977, Rizley 1978, Wenzloff and Grozier 1988). Anxious individuals have been found to have an unrealistic view of the danger or threat in situations (Mathews and MacLeod 1987, Fitzgerald and Phillips 1991), an attentional bias toward threatening stimuli (Mathews and MacLeod 1987), and an enhanced memory for anxiety-provoking situations (Ingram and Kendall 1987, Cloitre and Liebowitz 1991).

Taken together, the results of these studies suggest that disturbances in information processing are essential features of depression and anxiety. Theoretical assumptions and treatment strategies for CBT of many other conditions, including the eating disorders, substance abuse, personality disturbances, and psychoses, have been articulated. The reader is referred to publications on these topics for descriptions of how the cognitive model can be adapted for treatment of a wide variety of psychiatric disorders (Beck et al. 1990, Linehan et al. 1993, Freeman et al. 1989, Beck et al. 1993, Wright et al. 1993, Kingdon and Turkington 1995, Wilkes et al. 1994, Beck and Emery 1985, Wright 2004). Specific applications of cognitive and behavioral treatment strategies are described later in the chapter.

### Behavioral Model

The learning theories underpinning the behavioral therapies date to the work of Pavlov (Pavlov and Gantt 1928) and Skinner (1938). Voluminous laboratory research on learning in animals subsequently established certain lawful relationships in the acquisition and maintenance of behavior (Hull 1943, Mowrer 1947, Spence 1956). Moreover, demonstrations that abnormal or “neurotic” behaviors in animals could be either induced by repeated pairings of a noxious stimulus with a neutral one (i.e., classical conditioning) or shaped by controlling reinforcement schedules (i.e., operant conditioning) suggested that these
approaches were relevant to psychiatric illness as well (Watson and Rayner 1920, Masserman 1943, Skinner 1948, Wolpe 1952, Lindsley 1956).

By the late 1950s, there was considerable dissatisfaction with the medical and psychoanalytic models of psychopathological processes and treatment, particularly from within academic clinical psychology (Kazdin 1982). Such ferment was underpinned by the low levels of diagnostic reliability, even for well-established illnesses such as schizophrenia, (Kanfer and Saslow 1965, Mischel 1968) as well as by the lack of evidence supporting the effectiveness of psychodynamic psychotherapy (Eysenck 1952, Zubin 1953). Moreover, the revolution that has become modern psychopharmacology was still in its infancy and no alternative paradigm at the time had adequate scientific currency. The behavioral therapy movement was thus born, emphasizing the use of scientific principles of investigation with a focus on learned and measurable behaviors (Kazdin 1982, Beck et al. 1990). Further demonstrations of the utility of operant conditioning (i.e., behavior modification experiments in institutionalized, chronically mentally ill patients by use of contingent reinforcement or extinction (Ayllon and Azrin 1968, Ullmann and Krasner 1965) and counter-conditioning treatment of anxiety disorders (such as systematic desensitization (Marks and Gelder 1965, Paul 1966)) triggered a surge of enthusiasm for these more objective treatment methods. By the late 1970s, behavioral therapy had become the most academically influential model of treatment outside of the medical setting (Kazdin 1982, Beck and Emery 1985).

The behavioral model is based on the relatively straightforward “chain” of events and responses illustrated in Figure 91–3. Through the years, considerable effort and debate have concerned whether stimulus-response and response-reinforcement relationships could be invoked to account for the complexity of human behavior (Kazdin 1982, Staats 1964). In its maturity, behavioral therapy has broadened beyond an exclusive focus on observable behaviors (i.e., radical behaviorism) and now incorporates cognitive processes and other individual variables that affect learning (Bandura 1977a, Goldfried and Davison 1994). For example, in observational learning, the stimulus-response contingency relationship is established vicariously, by watching, reading about, or imagining the event in question. Reinforcement does not have to take place explicitly; it may occur vicariously, or it may simply be imagined. Other factors, such as the individual’s past history, inherent talents, or skillfulness of his or her pertinent response repertoire, help account for the wealth of inter-individual variability in stimulus-response relationships. Bandura’s cognitive–behavioral formulation of self-efficacy is one example of a “mental” construct that has abiding behavioral implications. This modifiable attitude or belief (roughly akin to self-confidence) influences persistence, willingness to try new things, optimism, and capacity to endure setbacks (Bandura 1977b).

One of the most important enduring experimental models of depression (learned helplessness) is the direct descendant of studies of animal learning (Seligman 1975, Maier and Seligman 1976, Miller and Seligman 1975). Learned helplessness is a state of behavioral passivity and apparent apathy induced by repeated exposure to noxious, yet inescapable, stimuli. The learned helplessness paradigm is based on a modification of escape or avoidance conditioning. A wide variety of species, ranging from goldfish to humans, can readily learn to avoid or escape from a setting when given advance notice (i.e., a light or tone) of an impending noxious event (i.e., a painful shock) (Maier and Seligman 1976). However, when escape is impossible (e.g., a dog is harnessed, or the walls of the experimental box are too high to be scaled), the animal is observed to be passive and inactive. During such “helplessness training,” the animal’s affect and behavior shift progressively from a state of apprehensive arousal (perhaps similar to human anxiety?) to one that may be analogous to depression. After repeated pairings, the animal will become unable or unwilling to escape from the stimulus when unharassed. The parallels to human experiences are obvious, although it is not known if the animal cognates helpless thoughts (“It won’t work… why bother to try…I’m better off just to be still”) (Oakes and Curtis 1982). Nevertheless, neurochemical and pharmacological studies underscore the phenomenological similarities between learned helplessness and depression (Weiss and Simson 1985, Willner 1991). Further, “helpless” dogs can be retrained to escape with techniques much like those used in behavioral therapy (Klein and Seligman 1976).

Over the past decade, several researchers have attempted to distinguish the extent to which the behavioral components of CBT are responsible for its therapeutic effect. The BA approach derives from the work of Ferster (1973), Lewinsohn (1974) and Rehm (1977). They hypothesized a link between avoidant (and withdrawal) behavior and the maintenance of depression. They recommended activation strategies that undermine avoidance, reduce antidepressant reinforcers, and increase positive reinforcement from the environment (Dimidjian et al. 2006). Recently, Dimidjian and colleagues (2006) described an “expanded BA model” that included increased focus on assessment and treatment of avoidance behaviors, the establishment/maintenance of regular routines, and behavioral strategies for targeting ruminations. This latter strategy emphasizes the functional impact of rumination thinking and moves away from the analysis of content toward a focus on direct, immediate experience (Dimidjian et al. 2006).

Cognitive and Behavioral Treatment Strategies

The cognitive and behavioral therapies are well known for their use of specific treatment techniques. Commonly used CBT procedures are directly linked to the theoretical constructs and empirical research of this school of therapy. Although techniques are given somewhat more emphasis in CBT than in some other forms of psychotherapy, there is still considerable room for therapists to be creative and flexible in developing a treatment plan. In fact, novice therapists sometimes focus too much on applying techniques at the expense of nurturing the therapeutic alliance and case formulation (Rush and Beck 1995). Development of a productive therapeutic relationship and an individualized case conceptualization should always take precedence over the implementation of specific cognitive or behavioral

techniques. A number of the more important CBT strategies are described briefly here. More detailed accounts of CBT interventions can be found elsewhere (Beck et al. 1979, Beck 1995, Barlow and Cerny 1988, Freeman et al. 1989, Persons 1989).

Collaborative Empiricism

As in all effective psychotherapies, the therapeutic relationship is important in CBT. However, interchanges between therapist and patient often differ from those observed in supportive or dynamically oriented treatment. One difference is that the therapist is responsible for managing the pace of the session. Using and adhering to an agenda makes each session as efficient as possible. Another difference is that CBT therapists adopt a therapeutic relationship that emphasizes: 1) a high degree of collaboration and 2) a scientific attitude toward testing the validity or usefulness of particular cognitions and behavior. This therapeutic stance is referred to as collaborative empiricism. The empirical nature of the relationship reflects that therapist and patient work together as an investigative team to develop hypotheses about cognitive or behavioral patterns, examine data, and explore alternative ways of thinking or behaving. At first, therapists usually spend more time teaching and explaining in CBT than in other forms of therapy, yet in the course of therapy, patients are actively engaged to become increasingly involved in the direction and the work of treatment. Critics of CBT sometimes suggest that the patient-therapist relationship is compromised by the therapist’s attempt to “replace” negative thoughts with positive ones. One jaded senior colleague referred to CBT as a “feel good therapy,” and another stated that CBT’s unspoken strategy was to teach people to lie to themselves. CBT is a cautiously optimistic therapy, but effective therapists do not use a “Pollyanna” approach to treatment. The data demonstrating CBT’s efficacy, discussed below, is the basis for our diagnostic optimism. The collaborative empirical stance requires that the therapist and patient work together to honestly appraise the validity of cognitions as well as of the adaptive or maladaptive aspects of beliefs and behaviors. If a negative assessment proves to be accurate (e.g., the patient actually has made serious mistakes, the individual’s spouse is highly likely to leave, or the patient has engaged in a repetitive self-defeating behavior pattern), then the therapist and patient need to work together in a problem-solving mode to develop a plan to cope with the problems at hand or practice more adaptive strategies for use in the future.

Wright and Beck, and others, have recommended several strategies for enhancing collaborative empiricism (Wright et al. 2003, Clark et al. 1999). These include: 1) adjusting the therapist’s level of activity to match the patients’ symptom severity or the phase of treatment; 2) encouraging the use of self-help procedures; 3) attending to the “nonspecific” variables important in all therapeutic relationships (e.g., empathy, respect, equanimity, kindness, and good listening skills); 4) promoting frequent two-way feedback; 5) devising coping strategies to help deal with real losses or implementing a plan of action to address maladaptive behavior; 6) recognizing transfERENCE phenomena; 7) customizing therapeutic interventions; and 8) using humor judiciously. It is also important to recognize and account for the wide variety of individual differences in cultural backgrounds, social attitudes, and expectations that each patient brings to the therapy encounter (Wright and Davis 1994).

Psychoeducation

Most forms of CBT integrate explicit psychoeducational procedures as a core element of the treatment process. Psychoeducational procedures are typically blended into treatment sessions in a manner that de-emphasizes formal teaching. There is a concerted effort to teach the patient why it is important to challenge automatic thoughts, identify cognitive errors, and practice implementing a more rational thinking style. Behavioral interventions are also preceded by psychoeducation to convey the background for principles such as extinction, reinforcement, self-monitoring, exposure, and response prevention.

There are a number of ways in which therapists employ psychoeducation in CBT. Perhaps the most important is the demonstration of basic concepts, which usually begins in the first therapy session (Beck et al. 1979, Thase and Wright 1991). Patients are more likely to grasp and implement therapy concepts when cognitive–behavioral principles are applied to situations that are personally significant. On occasion, therapists may give “mini-lectures” (Epstein et al. 1988) but an interactive and guided method of instruction, called Socratic questioning usually predominates (Beck et al. 1979, Overholser 1993a, 1993b, 1993c).

In the early phases of treatment, special attention is paid to socializing the patient to CBT. The basic cognitive-behavioral model is demonstrated, and expectations for both patient and therapist are conveyed. Some of the frequently used psychoeducational procedures in CBT include brief, impromptu explanations (often written on a chalkboard or a pad of paper to increase the chances of comprehension and retention) and reading assignments (bibliotherapy), such as Coping with Depression (Beck and Greenberg 1974), Feeling Good (Burns 1980), or Mind Over Mood (Greenberger and Padesky 1995), or Getting Your Life Back (Wright and Basco 2001). Psychoeducational initiatives typically become more complex as therapy proceeds. For example, detailed explanations and repeated exercises may be needed before the patient fully grasps abstract concepts such as attributional style or schemas.

As therapy progresses, homework assignments continue to explicitly reinforce and expand upon material covered during therapy sessions.

As in other forms of learning, individual differences in homework compliance may influence the progress of therapy. For example, some evidence suggests that homework compliance is correlated with treatment outcome (Whisman 1993, Burns and Spangler 2000). We have found that homework compliance is influenced partly by the therapist’s consistency, enthusiasm, and ability to integrate the assignments into the treatment plan.

Because psychoeducation can be time consuming and is a routine part of therapy, several investigators have developed computer programs that provide education on cognitive therapy, encourage homework completion, and actively involve patients in self-help exercises. One of the earliest programs, developed by Selmi and coworkers (1990, 1991), was found to be efficacious in the treatment of depression. Although this software relies completely on
written text for conveying information and is not available for clinical use, it demonstrated the potential benefits of computer tools for CBT. More recently, Wright and coworkers (1995, 2002, 2005) have introduced a multimedia form of computer-assisted CBT (“Good Days Ahead”) that uses full screen video and vivid graphics to engage users in the learning process. Research with this program has demonstrated strong effects on learning, high levels of acceptance by patients, and evidence for efficacy in the treatment of depression (Wright et al. 2002, 2005). Marks and coworkers (Shaw et al. 1999, Kenwright et al. 2001) have been using a text-based computer program (Fear Fighter) in Great Britain for treating anxiety disorders with exposure therapy. This group has reported significant increases in treatment efficiency when the computer program is used to provide psychoeducation and involve patients in exposure protocols (Kenwright et al. 2001). The use of computers as treatment adjuncts has been reviewed in several publications (Locke and Rezza 1996, Wright and Wright 1997, Wright 2004). Computer-assisted treatment is still in the early stages of development, but there appears to be considerable potential for using these new technologies to augment the process of psychotherapy.

Modifying Automatic Thoughts

The first step in changing automatic thoughts is to help the patient recognize when she or he is having them. The therapist is often able to illustrate the presence of automatic negative thoughts during the initial session by gently calling attention to a change in the patient’s mood. Such “mood shifts” can be excellent learning experiences that give personally relevant illustrations of the linkage between cognitions and feelings. Use of a mood shift to identify automatic thoughts is illustrated in the following interchange.

Therapist: I noticed a moment ago that your mood appeared to change. All of a sudden, you looked very sad. Do you mind if we talk about what was going through your mind?

Patient: No…but I’m not really sure what you mean…I guess I just felt that this therapy might be too hard to handle.

Therapist: I’d like to make a distinction between what you thought and what you felt. It looked like you were sad. Am I right? (patient nods) And, at about that time, you had the thought that this therapy might be too difficult? (patient nods) This could be an example of what we call a negative automatic thought. Let’s spend a few minutes to see if it is one, and if so, what it might mean.

One common misconception of CBT is that its practitioners disregard the role of affect or feelings in the etiology and treatment of psychiatric disorders. Actually, one of the principal components of CBT is the stimulation and modulation of emotion (see, for example, Figure 91–1). In fact, Beck referred to emotion as “the royal road to cognition” (Beck 1991). In contrast to experiential therapies, variations in emotion are used in CBT to establish links with cognition and identify errors in information processing. Getting in touch with feelings is thus not a goal in CBT but only a means by which therapy helps patients to gain greater control over the processes that influence their moods and behaviors.

Socratic Questioning

The most frequently used technique to uncover and modify automatic negative thoughts is Socratic questioning (or guided discovery) (Beck et al. 1979, Overholser 1993a, 1993b, 1993c). Socratic questioning teaches the use of rationality and inductive reasoning to ascertain whether what is thought or felt is actually true. The therapist models the use of Socratic questioning and encourages the patient to start raising questions about the accuracy and validity of his or her thinking. There are few formal guidelines for Socratic questioning (Overholser 1993a). Rather, therapists learn to use their experience and ingenuity to frame good questions that engage the patient in a process aimed at recognizing and modifying a biased or distorted cognitive style. Typical questions include: What ran through you mind at that time? What is the evidence that your impression is accurate? Could there be any alternative explanations? If this were true, what would be the worst thing that would happen? When guided discovery methods are not sufficient to draw out automatic thoughts, the therapist may turn to several alternative ways of eliciting dysfunctional cognitions, as described in the following.

Imagery Techniques and Role-Playing

Imagery techniques and role-playing are used when direct questioning does not fully reveal important underlying cognitions. When imagery is used, the therapist sets the scene by asking the patient to visualize the situation that caused distress. Although some patients can readily imagine themselves in a previous scene, many need prompts or imagery induction to encourage their active participation in the exercise. Several types of questions can be used to help frame the scene. These include inquiries about (1) the physical details of the setting, (2) occurrences immediately before the interaction, and (3) descriptions of the other people in the scene (Wright et al. 2003). In role-playing exercises, the therapist and patient act out an interpersonal vignette to uncover automatic thoughts or to try out a revised pattern of thinking. This technique is used less frequently than imagery by most cognitive–behavioral therapists and may be reserved for situations in which transference distortions are unlikely (Wright et al. 2003).

Thought Recording

Thought recording is one of the most useful procedures for identifying and changing automatic thoughts. This technique is first presented in relatively simple two- or three-column versions in the early stages of therapy. When the two-column procedure is used, patients are instructed to write down events in one column and thoughts in the other. Alternatively, they can record events, thoughts, and emotions in the three columns. The purpose of this exercise is to encourage patients to begin to use self-monitoring to increase awareness of their thought patterns. Next, the strength of the emotion and the believability of the automatic negative thoughts are rated on a scale of 0 to 100. In subsequent sessions, a more complex five-column thought record, the thought change record (TCR) is introduced (Figure 91–4). The fourth column of the TCR
encourages the patient to develop rational alternatives that rebut the automatic negative thoughts; the fifth column used for a reevaluation of the mood and cognitive ratings. Work on identifying cognitive errors can also be included in this form of thought recording.

Examining the Evidence

The examining the evidence procedure is a collaborative exercise used to test the validity of automatic negative thoughts. Cognitions are set forth as hypotheses rather than established facts. The patient is encouraged to write down evidence that either supports or refutes the automatic thought using a two-column form (i.e., pros and cons). For example, examining the evidence for the automatic thought “everyone always looks down on me” might reveal data in support of both sides of the question. It is likely that the patient will recall many times when he or she felt looked down on, treated disrespectfully, or criticized unfairly. On the other hand, it would be virtually impossible that others always perceive the individual in this way. Specific evidence of good job performance, positive relationships with relatives and friends, and successes in school or recreational activities may then be used to help counterbalance the patient’s negatively biased and overgeneralized automatic thought. More ambiguous examples may also be revealed in which the evidence does not clearly point in one direction or the evidence is not clear. In these situations, the therapist may suggest homework to collect additional information. Cognitive errors such as overgeneralization, catastrophic thinking, maximizing or minimizing, personalization, and all-or-nothing thinking are frequently revealed in these situations (see Table 91–1).

Next, the therapist helps the patient to revise the automatic negative thought in light of the evidence (e.g., “I often feel inferior to others, even when there’s no good evidence that I should feel that way” or “I have had a number of difficulties with my teachers and employers, but not all relationships have been bad and some have been very good”). The process thus moves from the patient’s general and globally negative interpretations to more specific, factually based statements.

When an honest appraisal uncovers evidence in support of negative cognitions, the therapist may choose to focus on the patient’s attributions of causality or internality. The patient who posits a negative attribution for poor work evaluation (e.g., “My performance was poor because I don’t have what it takes”) can usually be aided to consider a more neutral attribution (e.g., “My performance was poor because I was not prepared . . . my depression and lack of motivation contributed to this too”). The treatment plan may also be revised to develop better methods of coping in similar situations or to work on ways of remediating skill deficits. Sometimes, particular difficulties cannot be changed (e.g., physical handicaps,
markedly unattractive physical looks, or severe financial limitations). A trainee once remarked to one of us, “I’m not sure that CBT is the right treatment for my patient. He really is ugly and dumb, and as far as I can tell, no one has ever loved him!” Before turning supervisory attention to the patient’s problems, the therapist-in-training was engaged in a guided discovery exercise to clarify his assumptions and beliefs about the essential importance of physical beauty, intelligence, and romantic love. Subsequently, the patient was able to address these issues successfully in therapy as well.

Generating Alternatives

If automatic thoughts prove to be largely dysfunctional, the patient is encouraged to generate alternatives that are more accurate or factual. Many of the techniques discussed earlier can be used to help generate alternatives to automatic thoughts. Socratic questioning is used in therapy sessions to help the patient start to think more creatively. Also, psychoeducational procedures may be employed to teach brainstorming techniques. For example, the patient may be taught to use “expert testimony” or the opinions of someone who knows them well (i.e., a sibling, spouse, or best friend) to help develop less emotional and more rational alternatives. Thought records are often used to record alternatives to automatic thoughts. We often encourage patients to collect their thought records in notebook form for ongoing use. Figure 91–4 illustrates the use of rational alternatives during CBT for a depressed patient.

Many patients with depression, anxiety, and related conditions have relatively rigid cognitive styles that perpetuate dysfunctional thought and behavior patterns. For example, an individual who was given the homework assignment of challenging the automatic negative thought “I am a loser” presented the “realistic alternative” that “whenever I start thinking about how I’m a loser, I will force myself to stop thinking about it”. These thoughts about thoughts tend to undermine the credibility of the rational responses and may dampen the patient’s enthusiasm for using the procedure. The therapist may notice a particular facial expression or a change in the patient’s posture that suggests the existence of second-order thoughts. In such cases, more active therapeutic assistance may be needed. For example, the therapist may need to act as a teacher or coach in the area of adaptive cognitive functioning, rapidly rebutting automatic thoughts as they arise. Coping cards, which are index cards with helpful reminders on the use of CBT methods (in this case, rational responses to repetitive automatic negative thoughts), may be written during sessions and carried by the patient in his or her pocket, wallet, or purse for later use.

Cognitive–Behavioral Rehearsal

Cognitive–behavioral rehearsal is a treatment strategy that is particularly useful for preparing patients to put their experiences in CBT to work in real-life circumstances. After automatic thoughts have been elicited and modified through procedures described before, the therapist guides the patient in a series of rehearsal exercises to try out alternative cognitions in a variety of situations. By using imagery and role-playing scenarios to practice generating more adaptive cognitions, the patient may become aware of problems that could interfere with implementation of the new style of thinking. Further practice and targeted homework assignments may then be needed before alternative cognitions can be fully used. For example, the effects of cognitive–behavioral rehearsal may be extended to real situations by assigning homework to test use of the modified automatic thoughts.

Modifying Schemas

The emphasis in the early phases of therapy is usually on behavioral activation, identifying and changing automatic thoughts, and the reduction of symptoms. However, as the patient gains knowledge of cognitive–behavioral principles and acute symptoms begin to subside, the focus of the treatment sessions usually shifts toward work on the schema level. Schemas are relatively stable cognitive patterns that are the product of one’s beliefs, attitudes, and behavioral responses. Because schemas serve as underlying templates for the processing of new information, they play a major role in the modulation of more superficial cognitions (automatic thoughts), regulation of affect, self-esteem, and control of behaviors. Thus, schema modification is an important component of cognitively oriented therapies.

With Axis I disorders such as major depressive disorder and panic disorder, schema revision efforts are directed at correcting dysfunctional attitudes that may predispose the patient to symptomatic recurrences. After several months of productive therapy, schema modification may be placed in the context of reducing future vulnerability. CBT of personality disorders typically requires that a major portion of therapy be devoted to modifying schemas and related patterns of behavioral dysfunction (Beck et al. 1990). When schematic work cannot be fully addressed in time-limited therapy, the model of ongoing change may be introduced. Thus, the patient may begin to change her or his “life course” by development of a long-term self-help plan. Jarrett has proposed continuation and maintenance phases of CBT treatment of depression, and she argues for focusing on schema change in these phases of treatment if it is not accomplished in the acute phase of treatment (Jarrett et al. 2001).

Many of the techniques used to test and modify automatic thoughts are also used to identify and revise schemas. Psychoeducational interventions are usually required as a first step. Most patients are not aware of their “guiding principles,” so the therapist may need to begin by introducing and illustrating this concept. It is often useful to review the connection between automatic negative thoughts, basic assumptions, core beliefs, personal rules, and behavior patterns using material from the patient’s own experience (Wright et al. 2003). Socratic questioning is the core procedure used for schema modification (Beck et al. 1979; Overholser 1993c).

The downward arrow technique (Figure 91–5) is a particularly powerful way to move from surface cognitions to deeper cognitive structures (Friedman and Thase 2006). This technique describes asking the patient a question such as: “If this automatic thought were true, what would it mean about you as a person?” Another useful approach is to examine patterns of automatic thoughts from thought records to sort out common themes. The therapist may suggest themes based on her or his knowledge of the patient’s
automatic negative thoughts. In some situations, it may be helpful to have patients review a description of common pathological schemas to recognize some of their core beliefs (see Table 91–2). On occasion, it may be useful to have the patient write a brief autobiography to help elucidate the historical antecedents of the schema. Computerized learning programs can also be employed to help patients uncover their schemas and may be particularly useful in teaching patients how to change core beliefs (Wright et al. 2002, 2005). A study comparing computer-assisted cognitive behavior therapy (CCBT) with standard CBT found that depressed persons treated with CCBT had statistically greater change in dysfunctional attitudes than those treated with standard CBT (Wright et al. 2005).

Because schemas are so strongly held (in essence, they have helped define reality and mold behavior for years), they may require intensive work in a number of therapy sessions to undergo significant change. Sometimes long-term continuation and maintenance CBT is required to accomplish schematic restructuring. Therapists can select from a number of CBT techniques, including examining the evidence, listing advantages and disadvantages, generating alternatives, cognitive response prevention, and cognitive–behavioral rehearsal, as they attempt to modify schemas (Wright et al. 2003). Examining the evidence, generating alternatives, and cognitive–behavioral rehearsal were described earlier as methods of changing automatic thoughts.

Cognitive Response Prevention
In cognitive response prevention, the patient agrees to complete a homework assignment in which she or he must behave in a way that is inconsistent with the pathological schema. For example, a person with perfectionist attitudes may be assigned a task in which she or he must perform in a “so-so” manner. This is intended to activate the schema that is triggering automatic negative thoughts (e.g., “They’ll think I’m a sloth” or “I’ll never be trusted with an important assignment again”). By not responding to the perfectionist demands dictated by the schema, the individual, thus, has the opportunity to cope with the automatic negative thoughts consequent to this “rule violation.”

Listing Advantages and Disadvantages
The listing advantages and disadvantages procedure is particularly useful when a schema appears to have both adaptive and maladaptive features. Schemas that have damaging effects are often maintained because they also have a positive side. For example, the schema “I must be perfect to be accepted” can have significant benefits (e.g., hard work and attention to detail often lead to success in work or school). Nevertheless, because perfection is seldom possible, the individual may remain vulnerable to setbacks. Other schemas, such as “I’m a complete loser,” may not seem to have any advantages at first glance. However, even such a markedly negative basic assumption can reinforce other behaviors associated with it. For example, a person who believes that he or she is a loser may avoid making commitments, withdraw from challenging assignments, or refuse to exert a sustained effort to solve a difficult problem. This strategy may thus protect the person from painful setbacks at the expense of achieving successes. The advantages and disadvantages analysis provides the patient and therapist with essential information for planning modifications. Schemas are most likely to be revised when they take into account both the maladaptive and the adaptive features of the old basic assumption.

In general, it is recommended that patients keep a list of the schemas as they have been identified. The schema
list helps to focus the patient’s attention on the overarching nature of these maladaptive principles. Because schemas often become manifest only during periods of increased stress or symptom expression, they may appear to fade in significance as the patient begins to improve. For example, behavioral treatment programs that neither endorse nor aim to modify schemas are generally as effective as CBT in the short run. However, there may be a false security engendered by symptom relief. The cognitive model posits that the individual will remain vulnerable to the depressive impact of “matching” life events unless schema revision is accomplished (Friedman and Thase 2006).

**Behavioral Techniques**

In CBT, behavioral methods are usually integrated with cognitive restructuring in a comprehensive treatment plan. Behavioral strategies may be given a greater emphasis earlier in therapy with more severely symptomatic patients such as those with intense depression, bipolar symptoms, or schizophrenia (Beck et al. 1979, Thase and Wright 1991, Kingdon and Turkington 1995, Basco and Rush 1996, Scott and Wright 1997). Some cognitive-behavior therapists may rely primarily on behavioral interventions for conditions such as obsessive-compulsive disorder (OCD) or simple phobias. Commonly used behavioral strategies are described here in alphabetical order.

**Activity Scheduling, Graded Tasks, and Mastery-Pleasure Exercises**

Depressed people may spend excessive amounts of time alone or have tangible reductions of pleasurable activity. One of the earliest behavioral formulations of depression viewed the disorder as an “extinction state” resulting from the loss of reinforcers (Ferster 1973). Neurobiological changes accompanying prolonged stress may also dampen hedonic capacity, which in turn reduces the salience of reinforcers (Weiss and Simson 1930, Willner 1991).

Thus, the learned helplessness paradigm brings together behavioral and neurobiological domains. Depressed (i.e., goal-directed) behavior may elicit negative cognitions as well (Teasdale 1983). For example, depressed people often procrastinate against performing potentially “overwhelming” chores or tasks. Procrastination, in turn, elicits guilty thoughts and self-criticisms. Moreover, the depressive cognitive state increases the likelihood that individuals will minimize the positive value of the activities they are able to complete. As a result, it may also be said that depressed people suffer from a deficit of self-reinforcement (Rehm 1977).

One key to the behavioral approach for treatment of depression is the interruption of the downward spiral linking mood, inactivity, and negative cognition (Beck et al. 1979, Lewinsohn et al. 1982) (Figure 91–6). Completing an activity schedule is often the first behavioral homework assignment used in CBT (Beck and Greenberg 1974). Depressed patients are asked to begin to keep a daily log that is used to chart the relationship between their moods and their activities (Figure 91–7).

The nature of the activities is examined, and deficits in activities that might elicit pleasure or feelings of competence are identified. Next, assignments are made to engage in discrete pleasurable activities (or, in the case of an anhedonic individual, activities that were rewarding before becoming depressed). If needed, a Pleasant Events Schedule can be used to identify a “menu” of reinforcers (Lewinsohn et al. 1982). Following operant principles, activities that have been “high-grade” reinforcers in the past are scheduled during times of low moods or decreased activity. Next, subjective ratings of mastery or competence and pleasure are added to the activity schedule by use of a simple scale (i.e., 0 to 5), to avoid the tendency of dichotomous thinking. In this way, achieving a small degree of pleasure or mastery during a scheduled activity may be framed as an accomplishment, particularly early in the course of therapy.

---

**Figure 91–6** The downward spiral: interaction of affect, behavior, and cognition in severe depression. ANTs, Automatic negative thoughts.
The activity schedule may also be used, prospectively, to begin to tackle overdue chores or other dreaded activities. The graded task approach is based on the premise that in a depressed state, many normal activities are indeed too demanding for depressed patients to complete according to their usual standards or with their characteristic efficiency. Thus, the task is broken down into units or components. The first homework assignment is typically to identify and complete a minimally acceptable initial step. For example, a depressed businessman had concealed from his family that he was 6 months behind in paying their income taxes. When he tried to tackle the project, he thought, “I’m too tired to do it now…I can’t concentrate on this stuff…I’ll get more depressed if I try and fail.” These cognitions were so discouraging that he invariably postponed working on the taxes. As a result, he felt some relief immediately (a reinforcer for procrastination). However, within minutes he was plagued by automatic negative thoughts about the implications of putting off such an important task yet again. He also had shameful thoughts about what his family or friends would think about him when his secret was discovered. In this case, the man estimated that the task would require at least 10 hours if he were well. He also estimated that he had only about 50% of his normal energy and ability to concentrate. Therefore, 20 hours of work was planned in small blocks spaced out for the next 20 days. The first assignment was for the man to spend only 15 minutes organizing the forms necessary to do the overdue income taxes. The use of self-instruction and visual imagery can help patients to initiate action, and self-reinforcement after completion of each step furthers therapeutic momentum.

**Breathing Control**

An important component of CBT for anxiety disorders involves teaching the patient breathing exercises that may be used to counteract hyperventilation and/or reduce tension (Clark et al. 1985). Slow, deep breathing can have a calming effect not unlike progressive muscle relaxation (Bernstein and Borkovec 1973). These exercises also help to distract the patient from autonomic cues. After initial instruction and practice, the breathing skills are then applied anxiety-provoking situations of increasing intensity.

A note of caution is in order when teaching patients breathing control exercises. We have seen many patients who have misunderstood instructions and who have developed a pattern of overly deep breathing in response to stress. Instead of reducing anxiety, their breathing changes may increase the likelihood of hyperventilation. Thus, we typically recommend teaching patients about the pace and form of normal breathing patterns. Next clinicians can model normal, calm breathing as compared to rapid breathing typical of an anxiety attack. A second hand of a watch can be used to time breaths to slow them to a normal rate. Positive, calming images can also be used to reduce anxiety during the breathing exercises. Finally, we suggest that
patients regularly practice breathing exercises to reinforce their mastery of this anxiety management technique.

Contingency Contracting and Behavior Exchange

These strategies use the principles of operant conditioning (Skinner 1938) to modify the probability of occurrence of either undesired or desired behaviors. Malott and colleagues (1993) have written an excellent introduction to these methods. One key to applied behavioral analysis is understanding the control over the contingencies or reinforcers. Another important factor is that the terms of the contract are negotiated and should be specific and relatively straightforward. The positive contingency or reinforcer should be desirable and available shortly after the terms of the contract have been met. A paycheck is a good example of a contingency contract. Another common strategy is to chain, or pair, a high-frequency behavior (e.g., reading, watching television, or listening to music) to a low-frequency one (e.g., doing paperwork, doing housework, spending time with the children). Contingencies should generally start out relatively “rich” (e.g., 1 hour of video game time after 15 minutes of paperwork) and may be progressively “thinned” in time (Malott et al. 1993). Punishments or “response cost” contingencies are less widely used because of their negative affective responses (Azrin and Holz 1966).

Behavior exchange contracts are used with couples or families. For example, a distressed couple may voice dissatisfaction about two distinctly different behavioral tendencies, as illustrated.

**Partner 1:** You never help me out around the house.

**Partner 2:** That’s not true, I’m always pitching in. My problem is that on the weekends you never want to go out and have fun.

**Partner 1:** That’s partly true…but if I wasn’t so sick and tired of being stuck with all the housework, maybe I’d feel more like going out.

Rather than join the debate to ascertain which partner is right about what, the therapist suggests a contract to objectify the communication and increase the likelihood of mutually rewarding experiences. The contingencies used in the contract represent an exchange of desired behaviors. In the example, partner 1 desires assistance with specific household tasks (e.g., wash the dishes, fold the laundry). A desired frequency is also determined (e.g., nightly). For partner 2, a weekend outing is specified, and a mutually acceptable activity is chosen. The contract is written and signed by both parties and the therapist. Consequences for nonadherence may also need to be formulated.

Behavioral contracts may be particularly useful for assisting patients with medication adherence. For example, the therapist may help the patient identify barriers to taking medication as prescribed and then work out behavioral solutions that are written in contract form. Behavioral methods may include pairing medication taking with routine activities such as brushing teeth or meals, reminder systems, and reinforcement from significant others. We recommend explicit discussion of adherence problems and mutual agreement on a plan for taking medications when patients have difficulty in following the pharmacotherapy plan.

Desensitization and Relaxation Training

Systematic desensitization (Wolpe 1958) was one of the first behavioral strategies to gain wide acceptance. Systematic desensitization relies on exposure through a progressive hierarchy of fear-inducing situations. This procedure may use pairing of progressive deep muscle relaxation and visualization of the target behavior to decondition fearful responses. Systematic desensitization is useful for treatment of simple phobias, social phobia, panic attacks, and generalized anxiety (Wolpe 1982). Some evidence suggests that the active ingredient of systematic desensitization is exposure to the feared situation, first in imagination and later in reality, rather than an actual counterconditioning through the relaxation response (Kazdin and Wilcoxin 1976). Progressive deep muscle relaxation is also useful as a self-directed coping strategy and for treatment of sleep-onset insomnia (Goldfried and Davison 1994, Bernstein and Borkovec 1973).

Exposure and Flooding

The purpose of these strategies is to speed extinction of conditioned fear or anxiety responses. Behavioral theory dictates that fearfulness is reinforced by avoidance and escape behaviors (Rachman et al. 1986). Because the basis of the fear or phobia is irrational, the optimal strategy is to increase exposure to the feared activity without aversive consequences. In obsessive-compulsive disorder, the ritualistic behavior (e.g., hand washing or checking) is hypothesized to be reinforced by the relief of the anxiety associated with the compulsion (e.g., hand washing temporarily relieves the fear of contamination) (Rachman et al. 1986). In exposure, there are at least three means of fear reduction: autonomic habituation, recognition that the fear is irrational, and explicit enhancement of morale or self-efficacy that accompanies mastering the previously dreaded activity.

In graded or progressive exposure, a hierarchy is established, ranging from least-to-most anxiety-provoking situations. The individual is taught one or more ways to cope with anxiety (e.g., relaxation or self-instruction), and with the help of the therapist, the items on the hierarchy are worked through, one item at a time. Mastery is predicated on maintaining a sufficient duration of exposure for the fear to extinguish or dissipate. In some cases, imagery (exposure “in vitro”) is used before moving to exposure to the actual feared stimulus. Exposure may also be enhanced by guided support (i.e., the therapist’s presence during the session) or by use of coping cognitions for the duration of the exposure exercise.

Flooding, which relies on the same principles, dispatches with the hierarchical approach. The individual is exposed to the maximal level of anxiety as quickly as possible. The rationale for this accelerated approach is that it may hasten autonomic habituation. To be effective, flooding needs to be accompanied by response prevention. In response prevention treatment of obsessive-compulsive disorder, the individual agrees not to perform the compulsion despite strong urges to do so. Because obsessions are more private than compulsions, there can be less certainty that
the individual has fully participated in response prevention exercises (Stern 1978).

Participant modeling or contact desensitization is an accelerated form of exposure that produces rapid response in the treatment of simple phobias. The therapist serves as a supportive coach or guide and assists the patient through a progressively more demanding level of exposure to the feared situation. In most cases, lifelong fears of air travel, tunnels, heights, matches, dogs, water, or insects can be fully treated in a few hours of guided exposure.

Social Skills Training
Satisfactory interpersonal relationships require a complex set of skills, including reciprocity, respect for another's opinion, appropriate modulation of self-disclosure, the tempered ability to yield on some occasions and set limits at other times, the natural use of social reinforcers, and the capacity to express anger and resolve conflicts in a constructive manner (Lewinsohn et al. 1982, Hersen et al. 1984). Many people with psychiatric disorders suffer from either a state-dependent deterioration of these social skills or lifelong deficits of such skills. Once established, social skills deficits can increase the likelihood of experiencing stressful life events as well as “turn off” family members and other sources of social support that may help to buffer people against stressors (Coyne et al. 1987).

Problems as diverse as lack of assertiveness, temper “attacks,” excessive self-disclosure, monopolistic conversational style, under-reinforcement of significant others, and splitting (i.e., playing one against another) are amenable to social skills training. The methods employed include modeling (i.e., the therapist demonstrates a more effective alternative approach), role playing and role reversal, behavior rehearsal, and specific practice assignments. Often, the interpersonal anxiety and lack of self-confidence that go hand in hand with social skills deficits lessen in response to successful mastery of targeted assignments.

Thought Stopping and Distraction
Automatic negative thoughts and repetitive, intrusive ruminations are sometimes too intense to address with purely cognitive interventions. The technique of thought stopping capitalizes on the individual's ability to use a selectively narrowed attentional focus to suppress the intrusive cognitions. For example, a ruminative individual may be asked to visualize a large red stop sign, including its octagonal shape and white lettering. The command Stop! is paired with the image. The image and command are then used to interrupt a “run” of ruminations. At first, the technique is practiced in sessions at times when automatic thoughts or ruminations are mild. After initial success, the technique is next applied to more intensely disturbing cognitions. For individuals who find visualization difficult or ineffective, a rubber band may be worn on the wrist as a distractor. In a manner similar to that described before, the command Stop! is paired with a brisk snap of the rubber band.

Anxious patients may benefit from use of other distraction techniques to cope with panicky thoughts or increased sensitivity to interoceptive cues. Specifically, patients susceptible to panic often have a heightened awareness of otherwise normal physiological cues (e.g., alterations in heart rate, dryness in the throat, muscular tightness in the chest, or increased peristalsis). In turn, such sensitivity triggers automatic negative thoughts about an imagined impending calamity. Distractions such as counting backward, praying, or imagining a calming scene may be applied to direct attention away from the internal stimuli. Distraction techniques thus help the individual exert some control over the symptoms, permitting greater exposure and a growing sense of self-efficacy.

Formulation of Treatment

Indications for Treatment
The cognitive and behavioral therapies are indicated as primary treatments for adults suffering from several nonpsychotic, nonorganic Axis I disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV). These include major depressive disorder, dysthymic disorder, panic disorder, social phobia, OCD, PTSD, generalized anxiety disorder and bulimia nervosa (Wright et al. 2002). Cognitive and behavioral therapies are also useful as adjunctive treatments for patients with bipolar disorder (Basco and Rush 1996, Basco and Thase 1998, Lam et al. 2000, 2005b, Scott et al. 2003, and Zaretsky et al. 1999) and schizophrenia (Mueser 1998, Kingdon and Turkington 1995, Sensky et al. 2000). Although not extensively studied, cognitive and behavioral therapies incorporating coping skills training and relapse prevention strategies may also improve the outcome of individuals with substance abuse disorders (Wright et al. 2002).

Cognitive and behavioral therapies, like most other types of treatment, have not been studied widely in patients with Axis II disorders. However, the CBT approach to problem specification and explicit training in coping skills may be well suited for treatment of individuals willing to work on changing these habitual, ingrained patterns of thinking and behavior (Beck et al. 1990). Specific cognitive-behavioral formulations have been developed for each of the personality disorders, and modifications of CBT methods have been described for working with patients with Axis II problems (Beck et al. 1990). Linehan's model of CBT (dialectical behavior therapy) has been shown to be efficacious in reducing parasuicidal behavior in patients with borderline personality disorder (Linehan et al. 1991, Linehan et al. 1993, 2006).

Selection of CBT Treatment
Perhaps the greatest “rate-limiting step” in selection of CBT is having access to a well-trained therapist. However, there are a growing number of training programs in CBT, and centers for CBT are available in many cities throughout the world. Cognitive-behavior therapy is now a required element in the education of psychiatry residents and is the major orientation of many psychology graduate programs. The Academy of Cognitive Therapy (academycft.org) is a nationally recognized body that certifies therapists in this approach.

Selection of CBT for an individual patient should be based on the appropriateness of cognitive-behavior therapy for the treatment situation. Relevant questions include: Is the patient psychotic? If so, are there specific target behaviors and has psychopharmacological treatment been optimized? Does the patient suffer from a disorder for which there is evidence for the efficacy of CBT? Within groups of
patients with potentially treatable disorders, other indicators of responsivity include chronicity, severity, and comorbidity (Whittum 1993, Thase et al. 1993). A good general rule is that patients with acute, mild to moderately severe, mood and anxiety disorders are the best candidates for treatment with traditional CBT alone (Thase 1995). Patients with more chronic, severe, or complicated illnesses may be better candidates for combined treatment strategies than for CBT alone (Wright and Thase 1992, Thase and Howland 1994, Friedman 1997, Friedman et al. 2006). McCullough (2000) has developed a variant of CBT for chronic depression that has shown much promise alone and combined with antidepressant medication.

An outpatient trial of acute phase CBT typically ranges from 10 to 20 weekly treatment sessions (Wright and Beck 1983, Beck et al. 1979, Barlow and Cerny 1988, Persons 1989). However, shorter courses of treatment have been shown to be efficacious in some situations (Wright et al. 2005). Deterioration or noncompliance of the patient may warrant early termination of a treatment trial, and for certain chronic conditions such as borderline personality disorder and bipolar disorder, longer courses of therapy may be indicated (Beck et al. 1990, Linehan et al. 1993, 2006, Basco and Rush 1996). Jarrett and Kraft (Jarrett and Kraft 1997, Jarrett et al. 2001) have conceptualized treatment across the acute, continuation, and maintenance phases of the depressive disorder. We will discuss these phases of treatment in greater detail below. During treatment of major depressive disorder and panic disorder, a majority of patients who will benefit from CBT will show a significant reduction in symptoms within 6–8 weeks of starting therapy (Ilardi and Craighead 1994). Moreover, those who show a late response to CBT (i.e., between weeks 12 and 16) may be at high risk for subsequent relapse (Thase et al. 1992).

Issues of Gender, Race, and Ethnicity
The cognitive and behavioral therapies appear equally effective for men and women and people of various races (Dobson 1989, Thase et al. 1994a). As with other forms of psychotherapy, a productive CBT working alliance is based on mutual respect for individual differences (Wright and Davis 1994). For some persons with gender, racial, or ethnically related issues, it may be useful to select therapists with special skills or experiences (e.g., therapists specializing in gay and lesbian issues or posttraumatic stress syndromes due to rape or incest). It has been recommended that cognitive–behavioral therapists receive special training and supervision in methods of responding to gender, race, and ethnicity variations (Wright and Davis 1994).

Case Formulation
An individualized case conceptualization is used for directing the course of CBT. An analysis of cognitive–behavioral elements is combined with assessment of biological, social, interpersonal, and other possible influences on symptoms in order to produce a comprehensive formulation and treatment plan (Wright et al. 2006). Both cross-sectional (typical cognitive–behavioral responses to current environmental stressors) and longitudinal (developmental and life history contributions to develop schemas and core behavioral strategies) perspectives are considered. Details of how to perform cognitive–behavioral case formulations are provided in a basic CBT text with video illustrations (Wright et al. 2006). Also, the Academy of Cognitive Therapy Website (academyofct.org) has examples of written case conceptualizations.

Preparation of the Patient
The cognitive and behavioral therapies explicitly incorporate strategies to increase involvement and preparedness of the patient for therapy. Patients are typically encouraged to read relevant written materials describing the theory and strategies of the therapy; for common disorders, such as major depressive disorder and panic disorder, self-help manuals for patients are now available (Burns 1990, Greenberger and Padesky 1995, Wright and Basco 2002). It is likely that multimedia programs will have an increasing role in therapy preparation (Locke and Rezza 1996, Wright and Wright 1995, Wright et al. 2002). Regardless of the mode of application, patients beginning CBT need to become acculturated to the following: 1) they will be active participants in trying out new strategies; 2) they will be expected to do homework; 3) the outcome of therapy will be measured and strategies will be altered if they are not helping; 4) therapy will be focused on symptoms and social functioning and generally will be time limited in nature; and 5) the chances of success after treatment termination can be gauged by the patients’ incorporation of the therapy into their day-to-day life.

Phases of Treatment
Most cognitive and behavioral therapies may be viewed as using a three-stage process. The initial phase includes the processes of clinical assessment, case formulation, establishment of a therapeutic relationship, socialization of the patient to therapy, psychoeducation, and introduction to treatment procedures. The middle stage involves the sequential application and mastery of cognitive and behavioral treatment strategies. The second stage ends when the patient has obtained the desired symptomatic outcome. The final phase of therapy is characterized by preparation for termination. The frequency of sessions is reduced, and there is a steady transfer of the responsibility for the continued use of therapeutic strategies from the therapist to the patient. The third stage of treatment also focuses on relapse prevention. Strategies used at this point include anticipation of reaction to future stressors or high-risk situations, identification of prodromal symptoms, rehearsal of self-help procedures, and establishment of guidelines for return to treatment (Otto et al. 1993, Thase 1993). The failure to achieve a remission of depressive symptoms after 16–20 weeks of treatment may indicate a need for continuation phase treatment to achieve these goals and maintenance phase treatment for relapse prevention. Incomplete symptomatic remission after 20 weeks of CBT may also indicate the need for adding pharmacotherapy to the treatment plan as we discuss in greater detail below.

Intensity of Treatment
Outpatient CBT is normally conducted once or twice a week. In selected cases, three times weekly or even daily sessions may be useful, but the cost-effectiveness of such a labor-intensive approach is uncertain. One of the authors (J.H.W.), who often uses CBT in combination with pharmacotherapy
and computer-assisted treatment, has found that he can reduce sessions for ambulatory patients to every other week or to a shortened time frame (i.e., 20-25-minute sessions) when a good therapeutic relationship has been established and the patient has started to make significant progress.

When patients are seen in a day treatment hospital or inpatient setting, sessions are typically provided on a daily or every-other-day basis. Many programs blend individual and group therapies (Wright et al. 1993). In our experience, holding sessions more frequently helps to offset symptom severity and demoralization in severely ill patients (Thase and Wright 1991). The cost-effectiveness of more or less intensive cognitive–behavioral strategies has not been systematically studied. Nevertheless, we believe that therapists should adjust the frequency and intensity of treatment according to the needs of patients as well as the therapy resources that are available.

**Duration of Treatment**

In most cases, treatment is conducted in periods of 3–6 months. For those who begin therapy as inpatients, a similar period of aftercare is strongly recommended (Thase 1993). Unsuccessful therapy (e.g., failure to effect significant symptomatic improvement) should generally not continue past 12–16 weeks for outpatients. Therapy should not be terminated until patients have achieved symptomatic remission. Ideally, at least two or three sessions are planned on an every-other-week basis in preparation for termination.

**Outcome Assessment**

Cognitive and behavioral therapies are, in part, distinguished by their integrated use of objective assessment methods. For depression and the anxiety disorders, a number of well-established rating scales are available. Therapist-administered scales include the Hamilton Anxiety Rating Scale (Hamilton 1959) and the Hamilton Depression Rating Scale (Hamilton 1960) as well as the Yale-Brown Obsessive-Compulsive Scale (Goodman et al. 1989). Self-report assessments of symptoms include the Beck Depression Inventory (Beck et al. 1961), the Beck Anxiety Inventory (Beck et al. 1988), the Fear Survey Schedule (Wolpe and Lang 1964), the Fear Questionnaire (Marks and Matthews 1979), and the Hopkins Symptom Checklist (Derogatis et al. 1974). These scales are typically administered before treatment and repeated periodically (e.g., weekly or monthly) to monitor progress. The Dysfunctional Attitudes Scale, the Attributional Style Questionnaire, and the Automatic Thoughts Questionnaire may be used to evaluate distorted cognitions (Dobson and Shaw 1986). As suggested earlier, high residual levels of cognitive symptoms most likely convey an increased risk for relapse after termination of treatment (Thase et al. 1992, Simons et al. 1986, Fava et al. 1998a). Similarly, high scores on the Hopelessness Scale (Beck et al. 1974) have been associated with a high risk for subsequent suicidal behavior (Beck et al. 1985).

**Augmentation of Therapy**

One of the major methods of augmenting a cognitive and behavioral therapy is to add an appropriate form of pharmacotherapy. For example, a depressed or agoraphobic person who has not benefited much from eight weeks or more of CBT alone should probably be considered for pharmacotherapy. In such cases, the neurobiological substrate of the illness may be too severely disturbed to be responsive to the CBT without concomitant pharmacotherapy (Wright and Thase 1992, Jindal et al. 2002). In clinical practice, psychiatrists who are trained in CBT often combine cognitive therapy and pharmacotherapy from the beginning of treatment unless the patient expresses a strong desire to receive only a single form of therapy.

There are no contraindications to combining CBT and pharmacotherapy (Wright and Thase 1992). In fact, these modalities are highly compatible in theory and practice. As noted earlier, pharmacological stabilization is a prerequisite for CBT for some Axis I disorders (e.g., psychotic depressions, schizophrenia, and bipolar disorder). When these treatments are used in combination, the treatment team should have a well-defined division of labor, open lines of communication, and an explicit sense of collaboration. Treatment of patients with severe, refractory, or incapacitating mood and anxiety disorders may represent the best use of combined therapies (Thase and Howland 1994, Bowers 1990, Otto et al. 1994, Scott 1992, Whisman et al. 1991). Other strategies used to enhance CBT include increasing the frequency of visits, switching emphasis (i.e., from cognitive to behavioral or vice versa), or involving the spouse or significant others in the therapy (Beach et al. 1994, Emmelkamp and Gerlsma 1994). The last strategy has been shown to be particularly useful in cases of depression associated with marital discord (Jacobson et al. 1991, Beach and O’Leary 1992). Computer augmentation is a new addition to the tools available for CBT (Selmi et al. 1991, Wright and Wright 1997, Kenwright et al. 2001, Wright et al. 2002, Wright et al. 2005). Greater availability of personal computers with multimedia capability and increased pressure to reduce the cost of treatment may make this form of therapy augmentation a more common practice in clinical settings.

**Continuation and Maintenance Phase CBT**

When Beck and associates (Beck et al. 1979) described CBT in the late 1970’s depression researchers were primarily concerned with the issue of response to treatment—is psychotherapy or pharmacotherapy effective in reducing the symptoms of the disorder over a given time period (generally 1 month to 10 weeks for efficacy studies of the tricyclic antidepressants, 6–12 weeks for efficacy studies of SSRI’s and 12–20 weeks for studies of psychotherapies)? This phase of treatment has come to be called the “acute phase.” Because some patients do not completely achieve a remission of symptoms (their return to premorbid well state) and because many patients experience depression as a recurring illness, there is a need for longer-term treatment methods for major depression (Kupfer et al. 1986). Furthermore, incomplete remission of depression leads to recurrence, and this conveys many adverse economic, interpersonal and medical consequences (Thase 1992).

Over the past 18 years, studies conducted by Thase and coworkers at the University of Pittsburgh have identified and replicated correlates of relapse (return of symptoms during continuation phase treatment) and recurrence (return of symptoms after one year of remission of the illness) following the termination of acute phase CT (A-CT). Failure to achieve a complete remission of the index episode by the sixth week of A-CT is associated with a 3–5-fold increase in the subsequent risk of relapse or recurrence. Thase and
coworkers have found that between 50 and 60% of A-CT responders meet this criteria for risk and Jarrett’s group has demonstrated that an 8-month course of continuation-CBT essentially neutralizes this higher risk of relapse. C-CT focuses on the vulnerabilities for recurrent depression in three domains: biologic (genetics, biology, familial, and developmental), psychosocial (personality, interpersonal, and social), and cognitive (Jarrett et al. 2001). By identifying and modifying risks and vulnerabilities and learning more effective ways of managing mood symptoms, C-CT helps prevent relapse and recurrence.

Fava (Fava et al. 1994) has developed another interesting approach to reduce the risk of relapse, the sequencing of treatment depending upon the degree of response following acute therapy. He found that a 12-session course of CBT focusing on healthy lifestyle changes significantly reduced depressive symptoms (Fava et al. 1994), increased the likelihood of successfully withdrawing from antidepressants (Fava et al. 1995, Fava et al. 1998b), and decreased the risk of subsequent relapse after withdrawing antidepressant medications (Fava et al. 1998a). Other studies (Blackburn and Moore 1997, Paykel et al. 1999) support the strategy of using a short course of focused CBT to offset the risks of relapse and recurrence of major depression.

Efficacy of CBT

The cognitive and behavioral therapies are, as a class, the best studied type of psychotherapy. Numerous research studies have demonstrated the efficacy for a variety of Axis I disorders.

Mood Disorders

Most of the evidence for the effectiveness of Beck’s model of CBT for mood disorders is derived from studies of outpatients with major depressive disorder (nonbipolar, nonpsychotic subtype). There is no doubt that CBT is an effective treatment of major depression compared with a waiting list control condition (Thase 1995, Dobson 1989, Depression Guideline Panel 1993). Dating to an initial study by Rush and associates (Rush et al. 1977), one major research focus has been to establish the efficacy of CBT vis-à-vis antidepressant pharmacotherapy. At this time, eight controlled trials contrasting CBT and tricyclic antidepressants have been completed (McCullough 2000), as have a legion of studies using other designs and other comparison groups (Thase 1995, Jarrett and Rush 1994). Several meta-analytical reviews have been published (Dobson 1989, Depression Guideline Panel 1993, Gloaguen et al. 1998, Butler et al. 2006). Dobson found CBT to be superior to untreated controls, wait-list participants, pharmacotherapy with tricyclic antidepressants, and other therapies (Dobson 1989). Gloaguen et al. (1998) reported CBT was superior when compared with wait-list and placebo control conditions; modestly superior to other therapies. Recently Butler and colleagues (2006) reviewed meta-analyses of CBT and report that CBT was somewhat superior to antidepressants in the treatment of adult depression, OCD and several other disorders.

Thase and coworkers (2000) have reported on a retrospective comparison of consecutive cohorts treated with CBT or supportive counseling and pill-placebo. The findings of this analysis suggest that CBT has greater therapeutic effects than this competently administered control condition, the ideal comparator for pharmacology efficacy studies.

The results of the National Institute of Mental Health Treatment of Depression Collaborative Research Program (TDCRP) (Elkin et al. 1989), a large, controlled three-site clinical trial, initially appeared to be inconsistent with these findings. The study reported that CBT was as effective as the tricyclic antidepressant imipramine in the full sample, but neither CBT nor imipramine was significantly more effective than the control condition, supportive clinical management and pill-placebo. Furthermore, in the more severely ill patients or in patients with greater functional impairment, CBT appeared to be less effective than imipramine. Moreover, the study results suggested that CBT was slightly, although not statistically, less effective than interpersonal psychotherapy (IPT), especially when recovery (stable symptomatic remission lasting greater than 8 consecutive weeks) was the outcome measure examined. However, when this same cohort was observed over the course of 18 months of follow-up (Shea et al. 1992), it was determined that there was no significant difference among any of the treatments with respect to the number of patients that recovered and remained well. When the follow-up outcome of the CBT patients was reviewed, the authors found that CBT patients had the lowest rates of receiving some kind of treatment during the follow-up period and CBT patients had the lowest rates of relapse after 18 months. This led the authors to be encouraged about the prophylactic value of CBT.

Ablon and Jones (2002) also question the validity of the results of the psychotherapy findings of the Treatment of Depression Collaborative Research Program. The authors used actual transcripts of the IPT and CBT sessions and rated CBT and IPT sessions with respect to therapy process, therapy technique, and intervention styles. They report that both the IPT and CBT sessions adhered most strongly to the ideal prototype of CBT. In addition, adherence to the CBT prototype yielded more positive correlations with outcome measures across both types of treatment.

The acute-phase treatment findings of the Treatment of Depression Collaborative Research Program have raised questions about the suitability of CBT as a treatment of severe depression (American Psychiatric Association 1993). Alternatively, the adequacy of CBT provided in the Treatment of Depression Collaborative Research Program trial has been challenged by some who believe CBT therapists may need a longer period of training than that required to become proficient at interpersonal psychotherapy (Thase 1994). Nevertheless, in other group’s hands, CBT is fully the equal of pharmacotherapy (Blackburn et al. 1981, Murphy et al. 1984, Hollon et al. 1992). A recent three-site study by DeRubeis and colleagues randomized 240 moderately to severely depressed patients to CBT, antidepressant medication therapy (paroxetine), or placebo. Overall, CBT was shown to be as effective as antidepressant medication in the treatment of moderate to severe depression when provided by highly experienced cognitive therapists (there was a significant difference in site treatment interaction at one site) (DeRubeis et al. 2005). Furthermore, CBT has also been demonstrated to be effective for inpatients with severe and chronic depression (DeJong et al. 1986). An intensive CBT protocol has been demonstrated to be an effective treatment of 60% to 70% of unmedicated depressed
inpatients suffering from nonpsychotic major depression (Thase et al. 1993; Thase et al. 1991). There is additional evidence for the effectiveness of CBT in the treatment of severely ill depressed patients. In a large multisite randomized clinical trial of a difficult cohort of severe and chronically depressed patients, McCullough’s CBT-based treatment, The Cognitive–behavioral Analysis System for Psychotherapy, (Keller et al. 2000, McCullough 2000) has shown equal efficacy to the serotonin-norepinephrine reuptake inhibitor, nefazodone, each being effective in 55% of cases, but the combination of the two treatments produced an impressive response rate of 85% at the end of 12 weeks of treatment. Thus, a version of CBT modified to specifically address the problems of severe and chronic depression has shown efficacy. Further evidence supporting the use of CBT in severe depression is found in a study that suggests a benefit for CBT in preventing suicide attempts. These investigators compared CBT to enhanced treatment as usual in patients who recently attempted suicide. The CBT subjects had a significantly lower reattempt rate, were 50% less likely to reattempt suicide than the control group, and reported less severe depression and hopelessness in follow-up (Brown et al. 2005).

More recently, results of the multi-site, NIMH-sponsored Sequenced Treatment Alternatives to Relieve Depression (STARR*D) trial compared CBT as a second-step treatment in patients with unipolar major depression who did not receive benefit from an adequate trial of the SSRI medication citalopram (Thase et al. In press). In one comparison, participants were randomized to augmentation of citalopram with either CBT or medication (either bupropion SR or buprindle). CBT augmentation was as effective as medication augmentation, but the latter was associated with a more rapid response. In the second comparison patients were switched to CBT or medication (sertraline, bupropion SR, or venlafaxine XR). There were also no differences in the effectiveness of switch to CBT or medications, although pharmacotherapy was associated with significantly more adverse side effects. The authors conclude that for patients without adequate benefit from citalopram, CBT was an effective pharmacotherapy whether used as a switch or augmentation strategy (Thase et al. 2007).

Regarding the efficacy of combining CBT and medications, a meta-analysis of studies that examined treatment with medication alone (including tricyclics amitriptyline, clomipramine, nortriptyline, desipramine, and nefazodone) versus medication combined with CBT, Friedman and colleagues (2006) found the benefit favoring combination treatment over pharmacotherapy alone to be almost twice as great.

Interestingly, group CBT strategies for treatment of depression have been found to be nearly as effective as individual treatment in both direct comparisons (Ross and Scott 1985) and composite meta-analytical comparisons (Depression Guideline Panel 1993, DeRubeis and Crits-Christoph 1998). These studies, which have not yet dramatically affected practice habits, suggest that a significant savings in cost-effectiveness might be gained by more regular use of group treatments. One study (Ravindran et al. 1999) in dysthymic patients compared the efficacy of sertraline and group cognitive behavioral therapy, alone or in combination. These authors found the group CBT to be less effective than sertraline in alleviating clinical symptoms. However, CBT augmented the effects of sertraline with respect to some functional changes, and in a subgroup of patients it attenuated the functional impairments characteristic of dystymia.

Marital CBT also appears to be as effective as individual CBT in treatment of depression associated with marital discord (Jacobson et al. 1991, Beach and O’Leary 1992). When effective, this marital therapy also typically produces concomitant improvement in dyadic adjustment, whereas effects of individual CBT are primarily limited to symptom variables (Jacobson et al. 1991, Beach and O’Leary 1992). Because marital discord plays a major role in the pathogenesis of many depressive episodes, greater use of couples treatment strategies may be indicated (Beach et al. 1994, Baucom et al. 1990) and such strategies have been described (Baucom and Epstein 1990).

Some evidence suggests that CBT reduces the risk for relapse after termination of treatment (vis-à-vis patients withdrawn from antidepressants) (Simons et al. 1986, Evans et al. 1992, Blackburn et al. 1986a). In the study of Evans and colleagues, (Evans et al. 1992) CBT responders had the same degree of prophylaxis against relapse at more than 1 year of follow-up as did antidepressant responders treated with continuation phase pharmacotherapy (Figure 91–8). The risk for relapse after CBT may be particularly low for patients who achieve a complete remission before ending treatment (Thase et al. 1992). The use of CBT for relapse prevention by Fava’s group has been discussed (Fava et al. 1994). In a 12-month naturalistic follow-up study of patients who responded to acute phase treatment (see DeRubeis et al. 2005, discussed above), it was found that compared to successfully treated pharmacotherapy patients, CBT patients were significantly less likely to relapse, suggesting a possible enduring prophylactic effect for CBT (Hollon et al. 1992). These findings are supported by a study comparing patients with recurrent major depression who achieved remission and were assigned to continued treatment as usual with pharmacotherapy compared to such treatment augmented with a brief course of CBT over 2 years duration. These investigators found the addition of CBT resulted
in a significant protective effect, which intensified with the number of previous depressive episodes experienced (Brotting et al. 2005).

Other models of cognitive and behavioral therapy have also been studied in randomized clinical trials of major depressive disorder, and they have generally matched or exceeded the results of the antidepressant condition (McLean and Hakstian 1979, Wilson 1982, Hersen et al. 1984). In two studies, the combination of behavioral therapy and antidepressants resulted in significantly more rapid improvement (Wilson 1982, Roth et al. 1982). Behavioral strategies emphasizing self-control skills, problem-solving skills, and increased pleasant activities have also been consistently found to be superior to waiting list control conditions (Thase 1995, Depression Guideline Panel 1993).

Behavioral and antidepressants resulted in significantly more rapid improvement (Wilson 1982, Roth et al. 1982). Behavioral strategies emphasizing self-control skills, problem-solving skills, and increased pleasant activities have also been consistently found to be superior to waiting list control conditions (Thase 1995, Depression Guideline Panel 1993). Jacobson and colleagues (1996) performed a randomized trial comparing standard CBT with behavioral activation (BA), a condition in which cognitive interventions were proscribed. They found that BA produced as much symptomatic improvement as did the full CBT treatment. When the relapse rate in these groups was examined after 2 years, there was also no difference between the treatments (Goriner et al. 1998). More recently, Dimidjian and colleagues (2006) compared an “expanded BA model” to standard CBT and antidepressant medication (ADM) in a randomized placebo controlled design in adults with nonpsychotic major depression. In the less severe patients there was no difference between the treatments but among the more severely depressed patients, BA was comparable to ADM and both significantly outperformed CBT (in this condition behavioral techniques were proscribed). These results support the contention that more severely depressed patients require BA techniques to achieve symptomatic improvement and that BA is the preferred focus initially in such cases. As a result of these studies, Dimidjian and colleagues (2006) question the necessity of targeting negative thinking to achieve therapeutic response.

**Anxiety Disorders**

Controlled studies have established the efficacy of cognitive and behavioral therapies for generalized anxiety disorder, obsessive-compulsive disorder, simple phobia, social phobia, panic disorder, and agoraphobia (Wolpe 1982, Clum et al. 1993, Beck and Zebb 1994, Chambliss and Gillis 1993, Durham and Allan 1993, Butler et al. 1991, Barlow et al. 2000, Clark et al. 2006, Haby et al. 2006, Schuurmans et al. 2006). CBT has also shown to be effective in randomized clinical trials to be an effective treatment for anxiety disorders in older adults at the end of therapy and over 12 months of follow-up. These authors included patients with a wide range of anxiety disorders to allow generalization of their findings to a greater “real-world” population (Barrowclough et al. 2001).

CBT is very effective for simple phobias. The cognitive and behavioral treatments emphasizing progressive (graded) exposure, systematic desensitization, relaxation training, and the use of homework assignments are well established and are considered the psychotherapeutic treatment of first choice for the simple phobias (Wolpe 1982, Rachman and Wilson 1980, Chambliss and Gillis 1993).

CBT interventions are effective and frequently used interventions for the treatment of Obsessive-compulsive disorder (OCD). Whereas OCD is often refractory to traditional psychosocial treatments, response rates of 50% to 70% are typically reported in CBT trials (Emmelkamp and Beens 1991, Foa et al. 1992, Steketee 1994, Rufer et al. 2005). Behavioral strategies generally take precedence over cognitive interventions, with the paired strategies of exposure and response prevention proving particularly useful (Emmelkamp and Beens 1991, Foa et al. 1992, Salkovskis and Westbrook 1989). In a recent study, Whittal and colleagues (2005), found exposure and relapse prevention (ERP) to be equally effective as CBT in 59 completers at 3-months of follow-up. Although comparative studies are fewer, therapies emphasizing exposure and response prevention have been found to be comparable to antiobsessional pharmacological agents (such as clomipramine) in patients with behavioral compulsions (Foa et al. 1992, Marks et al. 1988). Interestingly, in a small study by Baxter and colleagues (1992), behavioral treatment of obsessive-compulsive disorder produced a change in glucose metabolism in the caudate nucleus (a putative neurobiological marker of obsessive-compulsive disorder) comparable to that observed in patients treated with pharmacotherapy. Several studies have examined whether pharmacological and cognitive–behavioral strategies can be used fruitfully in combination or in sequence (Kampman et al. 2002, Marks et al. 1980, Turner et al. 1980, van Oppen et al. 2005). Van Oppen et al. (2005) studied the long-term effectiveness of CBT alone, exposure in vivo and response prevention (ERP) alone, and CBT or ERP plus fluvoxamine. They concluded that (1) the prevalence of OCD declined in all three treatment conditions, (2) that these benefits were maintained for 5 years, (3) OCD complaints were more severe for treatment drop-outs than for completers, and (4) about half of the fluvoxamine patients continued antidepressant use. Regarding the question of treatment sequencing, Kampman and colleagues (2002) found the addition of CBT was effective in fluoxetine nonresponders.

**Generalized anxiety disorder and social phobia** are common and protean conditions, often presenting with much depressive and Axis II comorbidity. CBT emphasizing relaxation training, cognitive coping skills, social skills training, and graded exposure to feared situations has generally been shown to be superior to waiting list or nonspecific therapy control conditions (Blowers et al. 1987, Borkovec et al. 1987, Borkovec and Mathews 1988, Borkovec and Costello 1993, Butler et al. 1991, Durham et al. 1994, Heinberg 1990, Linden et al. 2005). An average of 60% to 80% of patients treated in clinical trials have responded to cognitive and behavioral methods (Gelernter et al. 1991, Power et al. 1990). In a controlled trial of patients with generalized anxiety disorder comparing CBT to behavioral therapy (BT) and a wait-list control group, results show a clear advantage for CBT over BT. There was a consistent pattern of change favoring CBT in measures of anxiety, depression, and cognition. A randomized, controlled trial in older adults with GAD of CBT versus a nondirective supportive psychotherapy found no significant differences between the treatments although both reduced worry anxiety and depression (Stanley et al. 1997). Linden and colleagues (2005) randomized 72 outpatients with GAD to either CBT or a contact control group and after the control period these patients were treated with CBT as well. They reported that CBT significantly reduced anxiety and that
the clinical effect remained stable over 8 months of follow-up. Their conclusion was that CBT is an effective treatment for GAD with an effect size comparable or larger than those reported for antidepressant medications. These results are supported by an 8-14 year follow-up study of CBT treatment which concluded that CBT and the complexity and severity of presenting problems appear to influence the long-term outcome of GAD (Durham et al. 2003). Another interesting study randomized 61 patients to either CBT or a nonspecific therapy control group to facilitate benzodiazepine discontinuation. They reported that 75% of patients in the CBT group ceased benzodiazepine use versus 37% in the control group and that a greater number of patients in the CBT group no longer met GAD criteria. However, discontinuation rates were twice as high in the CBT condition (Gosselin et al. 2006).

The comparative efficacy of cognitive and behavioral treatments and pharmacotherapy for panic disorder and agoraphobia is currently a topic of intensive investigation (Clark et al. 1994, Clum et al. 1993, Beck and Zebb 1994, Margraf et al. 1993, National Institutes of Health 1991, Ost et al. 2004, Otto and Deveney 2005). These treatments teach patients to disregard or deemphasize internal cues linked to sensitivity to anxiety while mastering behavioral self-control strategies such as breathing exercises and deep muscle relaxation. Cognitive strategies are also used in these models to decrease exaggerated thinking patterns (e.g., catastrophization) and reduce worrying.

In general, between 70% and 90% of patients treated with CBT become panic free within 2 to 4 months of beginning therapy (Clum et al. 1993, Chambliss and Gillis 1993, National Institutes of Health 1991, Otto and Deveney 2005). The specific models of CBT introduced by Beck and Emery (1985), Clark (1986), and Barlow and Cerny (1988) have been shown to be superior to waiting list or nonspecific control conditions (Margraf et al. 1993, Barlow et al. 1989, Beck et al. 1992). In a study using an across-subjects design, CBT is significantly superior to information-based therapy in reducing panic attacks in patients with panic disorder and secondary depression (Laberge et al. 1993). Meta-analyses (Beck et al. 1985, Chambliss and Gillis 1993) suggest comparability of CBT and pharmacotherapy (i.e., tricyclic antidepressants or potent benzodiazepines) during acute phase therapy. In one trial, the selective serotonin reuptake inhibitor fluvoxamine was superior to CBT (Black et al. 1993). However, in other studies, similar advantages favored CBT (Margraf et al. 1993, Klosko et al. 1990, Marks et al. 1993). In this regard, Heldt and colleagues (2006) found the results of a pilot study of cognitive therapy to be significant after one year in 63 patients who completed group CBT for panic disorder after failing to respond adequately to previous pharmacotherapy.

Even if it is comparably effective, the cost efficiency of pharmacologic treatment may be reduced (relative to CBT) by high rates of relapse after discontinuation of pharmacotherapy (DuPont et al. 1992, Noyes et al. 1991, Pollack et al. 1993). Evidence collected to date suggests that there may be fewer relapses after cessation of CBT compared with relapse rates after medication discontinuation (Otto and Deveney 2005). This prophylactic effect may be related to significant changes in neurophysiological sensitivity (Beck and Zebb 1994). For example, Shear and colleagues (1991) found that successful CBT resulted in a significant reduction in patients’ sensitivity to sodium lactate, a biological probe that reliably induces panic attacks in a significant number of patients susceptible to panic.

As with treatment of depression, CBT has shown value when it is used sequentially to reduce the risk of relapse after withdrawal of pharmacotherapy (Otto et al. 1993, Spiegel et al. 1994). To date, evidence does not indicate that the combination of CBT and pharmacotherapy yields a strongly synergistic effect (Clum et al. 1993, Marks et al. 1993, Hegel et al. 1994, Mavissakalian and Michelson 1986, Gelder 1998).

There is also interest in the application of CBT to posttraumatic stress disorder. A recent review of controlled outcome studies indicated that CBT is the psychological treatment of choice and that is more effective than eye movement desensitization and reprocessing (Bryant and Friedman 2001).

**Eating Disorders**

Many research studies have demonstrated the efficacy of CBT for bulimia nervosa (Agras et al. 1992, 1994, 2000, Fairburn et al. 1991, 1992, 1993, 1995, Garner 1992, Goldbloom et al. 1997, Walsh et al. 1997). Reviews of controlled studies of CBT have found strong evidence for the efficacy (Wilson 1999, Ricca et al. 2000) and theoretical utility (Reas and Grilo 2004) of CBT. Combined cognitive and behavioral therapy has been shown to be superior to a behavior therapy alone approach to bulimia (Thackray et al. 1993). At the six-month follow-up assessment after treatment, 69% of the subjects who received CBT reported no binge eating and purging as compared to 38% abstinence in the behavior therapy group and 15% abstinence in the attention placebo group. In a comparison of CBT and a guided self-help condition, subjects in both treatment conditions showed a significant decrease over time in binge eating and vomiting frequencies (Bailer et al. 2004). Reviews of research on combined CBT and pharmacotherapy for bulimia have found that CBT has an additive effect to antidepressant therapy (Wilson 1999, Ricca et al. 2000). But, there appears to be no advantage to adding medication to CBT for anorexia nervosa. In addition, CBT has also been advocated for binge eating disorder (Vaidya 2006).

**Bipolar Disorders**

There are several randomized control trials of CBT in patients with bipolar disorder. Cochran (1984) studied whether CBT improved lithium compliance at 6 and 12 months after treatment as compared to a control group. The results indicated no difference in lithium compliance on the self-reports, informant-reports, or serum lithium levels, but the physician (who was not blind to which group the patient belonged) reported more compliance. Scott et al. (2001) reported the results of a pilot study of cognitive therapy in patients with bipolar I (n=34) and bipolar II (n=8) disorders. Half the patients were assigned to immediate CBT or 6-month wait-list control, which was then followed by a course of CBT. At six-month follow-up, subjects who had CBT showed statistically significantly greater improvement in symptoms and functioning than those in the waiting-list control group. In the 29 patients who eventually received CBT, relapse rates in the 18 months after commencing CBT showed a 60% reduction in comparison with the 18 months
prior to commencing CBT. Seventy percent of the subjects who commenced CBT found it to be a highly acceptable form of treatment. Immediately after receiving CBT changes in symptoms and functioning were significant but these changes were not maintained at 6 months after CBT was finished. Interestingly, in the CBT group, reductions in depressive symptoms were more robust than reductions in manic symptoms. Interestingly, this same group (Scott et al. 2006) recently reported on a subsequent study of 253 bipolar subjects, which found no overall benefit of CBT, compared to treatment as usual, in reducing relapse rates. However, CBT was effective in preventing relapse in persons who had fewer than 12 previous bipolar episodes.

Another line of research into the benefit of CBT for bipolar patients examines using CBT to prevent relapse in patients with bipolar disorder who are taking mood stabilizer medications. The authors modified CBT by (1) a psychoeducational component that modeled bipolar illness as a stress-diathesis illness; (2) adaptive CBT skills to cope with producers (identifying the onset of symptoms of bipolar disorder characteristic of the patient’s illness pattern); (3) promoting the importance of circadian regularity by emphasizing the importance of routine and sleep; and (4) dealing with the long-term vulnerabilities and difficulties of the illness. Therapy consisted of 12–20 sessions and lasted 6 months and outcomes were measured at 6- and 12-month points. The CBT group had significantly fewer bipolar episodes, higher social functioning, better coping strategies for bipolar problems, evidence of less fluctuation in symptoms of mania and depression, less hopelessness, better medication compliance, and they used significantly less neurologic medication (Lam et al. 2000). Recently, Lam and colleagues (2005a) reported on the 30-month follow-up of this cohort. They report that over 30 months the CBT group had significantly better outcome in terms of time to relapse. Patients in the CBT group also had significantly fewer days in bipolar episodes. However, there was no significant additional CBT effect in relapse reduction over the last 18 months of the study period, suggesting the need for booster or maintenance CBT treatment sessions. Additionally, this group found that CBT plus mood stabilizers was superior to mood stabilizers alone in terms of cost-effectiveness for those with frequent relapses of bipolar disorder (Lam et al. 2005b).

Another recent study by Bull et al. (2006) observed that 6 months of CBT for bipolar disorder had clinical benefit in reducing depression, dysfunctional attitudes, and global ratings of symptom severity. There was a trend for lower relapse rates in patients treated with CBT. These authors note that the short-term effects of CBT treatment were greater than the long-term effects, which may suggest that maintenance phase therapy may be needed to sustain the therapeutic effects of CBT in bipolar patients. In the recent, multisite, NIMH-sponsored study of the effectiveness of treatments in bipolar disorder, the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study, several intensive psychotherapies were compared to a minimal psychosocial intervention (called collaborative care) (Miklowitz et al. 2007). The intensive psychotherapies included CBT, family-focused treatment (FFT) and the Interpersonal and Social Rhythm Therapy (IPSRT). These investigators found that despite equal rates of attrition across groups, patients receiving intensive psychotherapy had significantly higher year-end recovery rates and shorter times to recovery than patients in the collaborative care group. These patients were also 1.58 times more likely to be clinically well during any study month than those in collaborative care. No statistically significant differences were observed in the outcomes of the three intensive therapies.

Other Disorders

Although CBT is not as well established as a primary treatment for other disorders, promising preliminary data are available in studies of borderline personality disorder (Linehan et al. 1991, Linehan et al. 1993, Salkovskis et al. 1990). Cognitive and behavioral therapies have also been studied in substance abuse disorders and tend to be more effective than standard counseling approaches only with patients with concomitant psychiatric illness (Woody et al. 1984, Carroll et al. 1994, Higgins et al. 1994). The directive methods employed by cognitive–behavioral therapists may help to lessen the resistance characteristic of more sociopathic substance-abusing patients, who may have limited ability to make use of reflective and insight-oriented strategies (Kadden et al. 1989).

For the psychotic Axis I disorders, including schizophrenia and bipolar disorder, the cognitive and behavioral therapies have been shown to be useful adjunctive treatments for patients stabilized with appropriate psychotropic agents. The first trials of CBT for psychosis were uncontrolled but suggested that this treatment approach could be used effectively for hallucinations, delusions, and other symptoms of schizophrenia (Fowler and Morley 1989, Chadwick and Birchwood 1994, Kingdon and Turkington 1991). Subsequently, several randomized controlled trials have found that CBT can add to the effect of medication (Drury et al. 1996a, 1996b, Kuipers et al. 1997, Tarrier et al. 1993, Sensky et al. 2000).

For example, Drury and coworkers (1996a, 1996b) observed that positive symptoms improved more in hospitalized patients who received CBT than those patients receiving nonspecific and supportive treatment. This research group also observed reduced time required for recovery in those treated with CBT. Sensky and coworkers (2000) studied 90 patients with schizophrenia who had persistent, drug resistant symptoms. In this study both forms of psychotherapy (CBT and an equal amount of time in “befriending”) were effective at the end of active treatment. However, 9 months after treatment subjects who received CBT had significantly lower ratings on measures of positive and negative symptoms.

Conclusion

The cognitive and behavior therapies are based on well-articulated theories that have a strong empirical basis. These therapies emphasize objective assessments and use of directive interventions aimed at reducing symptomatic distress, enhancing interpersonal skills, and improving social and vocational functioning. Cognitive interventions are focused primarily on identifying and modifying distorted thoughts and pathological schemas. Behavioral techniques to increase exposure, increase activity, enhance social skills, and improve anxiety management are useful modalities, and can complement or amplify the effects of cognitive...
strategies. Similarly, the cognitive perspective can add depth to behavioral models for therapy by teaching patients how to recognize and modify their attitudinal vulnerabilities.

The cognitive and behavioral therapies are the best-studied psychological treatments of major depressive, panic, generalized anxiety, and obsessive-compulsive disorders. Overall, there is good evidence for the effectiveness of these interventions within these indications. Cognitive and behavioral therapies are being adapted for adjunctive use with pharmacotherapy for treatment of bipolar disorder and schizophrenia. There are no contraindications for use in combination with pharmacotherapy. The cognitive and behavioral therapies have become one of the standard psychosocial treatment approaches for mental disorders.

Introduction
Family therapy is psychotherapy that directly involves family members in addition to the identified patient, and/or explicitly attends to the interactions among family members (Hoffman 1985, Pinsof and Wynne 1995). Family therapy thus engages relational and communicational processes of families and social networks as a primary context for solving clinical problems or treating psychiatric disorders, even though one family member may be the sole bearer of distress or symptoms. By educating family members or altering family patterns of relating or communicating, such clinical problems as depression, anxiety, marital conflict, or disruptive childhood behavior can be resolved or attenuated.

Although social workers met therapeutically with families as early as the late 1880s, family therapy as known today emerged in the 1940s (Broderick and Schrader 1981). The sudden reuniting of families at the conclusion of World War II precipitated marital discord, divorce, delinquency, and emotional breakdowns, leading to requests for professional help (Goldenberg and Goldenberg 1980). The subsequent failure of psychoanalysis to find therapeutic breakthroughs for such problems as schizophrenia and juvenile delinquency shifted attention away from the interior emotional life of individuals to their family relationships as a potential point of intervention. During the late 1940s and 1950s isolated pockets of family therapy practitioners proliferated across the US. Each group brought its unique perspective to the observation of families, and from each a distinct “school” of family therapy developed (Slovik and Griffith 1992).

Over the ensuing decades, these different clinical approaches to family therapy began coalescing into clinical traditions defined by their core theoretical assumptions and methods, supported to varying extents by research. Each of the major family therapy traditions has contributed to the repertoire of mental health professionals its unique framework for understanding clinical problems, and an associated set of interventions. Some approaches have insisted that whole families be involved in most sessions, while others have worked focally with individuals or subunits of families. The different family therapy traditions can be usefully contrasted by comparing how each structures perceptual, cognitive, and executive processes when clinicians work with families—from each of these perspectives.

• What does a therapist look for?
• What does a therapist think about?
• What does a therapist do?

When multiple traditions or schools of psychotherapy are considered, the question naturally arises: which works best? There has been ample clinical evidence that each tradition “works,” somewhat better than others for particular problems, or with particular families, or in the hands of particular therapists, or at different phases of recovery from illness (Pinsof and Wynne 1995). The evolution of mental health services, however, has led not to a dominance of any one of the family therapy traditions, but to comprehensive family-centered programs that now draw broadly from multiple traditions. These family-centered programs for preventing or treating psychiatric disorders have been validated to a substantial extent in empirical research studies, as discussed below. Different family therapy traditions are themselves best regarded as different sets of ideas and interventions to be valued as potential tools within comprehensive, multimodality treatment programs.

It should also be noted that the different family therapy traditions bear features in common. Each views a symptomatic patient not only as an individual, but as a family member in a family system organized by (1) affiliative bonds among its members, (2) a power hierarchy in terms of decision-making and who has what access to information, and

Clinical Vignette 1

Bill and Roberta requested therapy due to the fights they were having over parenting their two stepchildren. Roberta’s 11-year-old son, David, with significant problems from attention-deficit disorder with hyperactivity, lived with them. Bill’s 10-year-old son, whom he coparented with his former wife, lived with them every other weekend and one night each week. The arguments were so severe that they threatened the marriage.
(3) shared values that constitute a sense of family identity. Each family therapy tradition addresses in its own way a family’s emotional relationships among its members, its organization as a system, and the meaning of its values in order to effect therapeutic change in the symptomatic member.

In the following paragraph we will illustrate the range of perspectives and interventions available in the different traditions by examining, in turn, how psychodynamic, structural, strategic, cognitive–behavioral, and postmodern family therapy traditions each might approach an identical clinical problem. The problem is explained in Clinical Vignette 1.

**Psychodynamic Family Therapy**

Psychodynamic psychotherapy helps family members solve relational problems by understanding better how emotional processes influence the perceptions, feelings, and actions of those involved. The early psychoanalysts noted that intrapsychic processes of an individual powerfully shape his or her interactions with other people, and most so in emotionally intimate relationships of couples and families. Extending the concepts and language of psychoanalysis to family behavior was a logical next step for those who began meeting with parents and children, couples, and whole families. In particular, object relations theory provided a bridge from the individual intrapsychic processes to the interpersonal processes of families (Scharff and Scharff 1987, Framo 1991, Slipp 1991).

The era of ascendancy for psychoanalytic thinking coincided with development of general systems theory and cybernetics as conceptual models for understanding, controlling, and predicting the behavior of complex physical and biological systems. Psychodynamic family therapists adopted such systems concepts as boundaries and levels of hierarchy, and such cybernetics concepts as negative feedback and homeostasis. Such systems described complex family interactions, while preserving the psychological language of psychoanalysis in describing such motivational processes as projective identification.

**What to Think About.** In order to understand how one family member acts in relation to other family members, psychodynamic family therapy concentrates upon motivations, conflicts, defenses, and relationships from the past that currently influence the present. Family interactions are explained in terms of internal processes within individual family member. Therapeutic change is sought through family members gaining conscious insight into previously unconscious processes that have been generating problems in family relationships.

**What to Look For.** Psychodynamic family therapy grounds its work in historical information. Extensive individual and family histories are elicited in order to understand family members’ experiential models of the world. These experiential models govern how meanings are attributed to such family patterns as rules for how people should respond and models for being a man or a woman, husband or wife, or mother or father. These models have developed out of each family member’s personal history, the family’s history and mythology, and their cultural history. Some of the diagnostic patterns upon which psychodynamic family therapists focus when assessing families include the following.

- **Projective identification.** Projective identification is an ego defense to which psychodynamic family therapists have attributed a crucial role in conflictual family relationships. In projective identification, one family member (a parent or couple partner) relates to another family member (a particular child or the other couple partner) as if he or she embodied a projected part of self. The projecting family member then interacts with, or relates to, the projected part of self as if that part were an internalized part of himself or herself. The projecting family member unconsciously prompts the other to conform to the way in which he or she is being perceived, evoking in the other the associated feelings and behaviors as if they were authentic. When viewed from the outside by the therapist, it appears as if the two are in collusion with one another in order to sustain these mutual, projected perceptions. Projection of disavowed elements of the self, whether positive or negative, has the effect of charging the relationship with emotion that has been transposed from an intrapsychic sphere into an interpersonal one. Acted out interpersonally, it serves to decrease psychic anxiety at the expense of an increase in tension and impasse in the relationship.

- **Unresolved grief.** When a family member, or the family as a whole, has not fully grieved losses, the family can become developmentally frozen. While so preoccupied with the past, it can be difficult to focus enough time and energy on current problems.

- **Clarity of ego boundaries and capacity for intimacy/separateness.** Conflictic family relationships can represent an alternative method for stabilizing emotional distance when the involved family members lack the emotional maturity to regulate closeness and distance in more differentiated ways. This has been a common model for understanding couples who chronically fight yet never separate.

**What to Do.** Psychodynamic family therapists employ the fundamental tools of psychodynamic psychotherapy (opening emotional expression, clarifying communications, encouraging family members to speak from the “I” position, and interpretation of unconscious conflicts) to resolve projective processes, cutoff relationships, and difficulties in modulating closeness and distance in family relationships. Psychodramatic techniques, such as doubling and role reversal, can play useful roles in implementing these interventions (Blatner 1994). Therapeutic rituals are particularly useful in facilitating grief over losses and in facilitating developmental transitions, such as a young adult leaving home or a couple moving into retirement years (Imber-Black and Roberts 1992). For example, a therapist can suggest to family members that they gather over dinner with their recent college graduate, both to review family photographs with fond remembrances from her childhood and to hear her speak as an adult about her future plans for a career. Such occasions marking existential time provide an opportunity to grieve losses, to embrace a new future, an to express openly the sadness and joy of each.

Psychodynamic family therapists commonly utilize family genograms when taking a family history. A genogram can provide a map of family life over time in a visual form.
that can help family members grasp interactional patterns, particularly when the patterns extend across the generations (McGoldrick and Gerson 1985). A psychodynamic family therapy with Roberta and Bill might begin as given in Clinical Vignette 2.

**Clinical Vignette 2**

The therapist asked to meet with Roberta and Bill as parents before meeting with 11-year-old David. Utilizing a genogram she elicited a history, not only of their current nuclear family but also for Roberta’s and Bill’s parents’ and grandparents’ generations. She learned that Roberta had been ashamed of her family of origin. She characterized her mother as “a slut who stayed out all night.” Eventually, Roberta’s mother was diagnosed with bipolar disorder, but it was poorly controlled with multiple hospitalizations. Roberta was the oldest of six children, all from different fathers. Roberta stated, “Nobody raised me, but I raised my brothers and sisters.” At age 12 years, a new stepfather entered the family but was verbally and emotionally abusive towards her. Consequently, “stepfathers” have had a negative connotation in Roberta’s mind. Out of her childhood experiences, Roberta came to believe that “I’m okay so long as I can be on my own, because I can’t trust or depend on anybody.”

Bill, on the other hand, was the second oldest child in a strict, rigid family. Both parents were emotionally and physically abusive, his father more than his mother. At one point Bill tried to stop his father from beating his older brother and was himself badly beaten. Although angry and afraid of his father’s violence, Bill also blamed his brother’s out-of-control behavior for provoking his father. At 16, Bill pinned his father to the wall and said, “If you hit me, I’ll kill you.” His father never hit him again. Bill’s mother was also abusive. Once she kept hitting him across the face, and he responded by telling her, “I hope you like it” and let her hit him until she finally stopped.

The therapist used the genogram session as an opportunity for Roberta and Bill to hear the stories from each others’ childhoods that so charged with emotion their interactions. The therapist observed how Roberta’s aversive experiences with a stepfather put her on guard with Bill and made her more protective of David. The therapist also interpreted to them how “I’m okay so long as I can be on my own, because I can’t trust or depend on anybody.”

Bill, on the other hand, was the second oldest child in a strict, rigid family. Both parents were emotionally and physically abusive, his father more than his mother. At one point Bill tried to stop his father from beating his older brother and was himself badly beaten. Although angry and afraid of his father’s violence, Bill also blamed his brother’s out-of-control behavior for provoking his father. At 16, Bill pinned his father to the wall and said, “If you hit me, I’ll kill you.” His father never hit him again. Bill’s mother was also abusive. Once she kept hitting him across the face, and he responded by telling her, “I hope you like it” and let her hit him until she finally stopped.

The therapist used the genogram session as an opportunity for Roberta and Bill to hear the stories from each others’ childhoods that so charged with emotion their interactions. The therapist observed how Roberta’s aversive experiences with a stepfather put her on guard with Bill and made her more protective of David. In contrast, Bill’s experiences with his father and parents, people he described as “having out-of-control behavior,” led him to overreact to his father’s attention-deficit/hyperactivity disorder (ADHD). Each of them, operating out of their own well-meaning logic, was making the problem worse. The therapist then used psychodramatic techniques and had them create and then practice ways in which they could work as a team in disciplining David.

### Structural Family Therapy

Structural family therapy considers problems involving a particular family member to be inextricably linked to the organizational context of the entire family. It solves problems by changing the family’s organizational context. Structural family therapy thus emphasizes an understanding of a family in terms of the family rules and roles that shape its members’ actions.

Family structure is the internal organization of the family that dictates how, when, and to whom family members relate while carrying out the various functions of the family (Aponte and VanDeusen 1981, Colapinto 1991). Some important elements of family structure for clinical work are boundaries, hierarchy, alliances, and coalitions.

- **Boundaries.** Rules defining who participates and how, in particular moments of family life. For example, a boundary around the parental couple means that the children are included in discussions of certain topics but not in others.
- **Hierarchy.** Relative influence of each family member upon the outcome of an activity. For example, all family members may have opinions about spending money, but the parents as a couple typically have the final say.
- **Alliances.** Family members joining together to support another family member. For example, older children may join the well-parent in organizing to parent younger children if the other parent were to become seriously ill.
- **Coalitions.** Family members joining together in opposition to another family member. For example, a grandchild and grandmother might quietly ally together for the child to stay up late at night against the mother’s wishes when the child is at grandmother’s house.

The family structure should provide cohesive and flexible responses to life stresses so that important family functions—parenting, providing income, marital intimacy, recreation, and other activities—can be carried out successfully, and family members can grow and mature in their individual lives.

**What to Look For.** A structural family therapist observes closely the flow of family structures as family members talk about and interact together around the presenting problem of the therapy. The therapist wishes to witness how sequences of family behaviors are enacted during interactions in the sessions, particularly the occurrence of a symptom as it is embedded within different configurations of organized family interactions. The therapist observes how boundaries, hierarchy, alliances, and coalitions are associated with the presenting symptom, as well as any repetitive behavioral sequences (verbal or nonverbal) that involve symptomatic behavior.

**What to Think About.** The structural family therapist considers the problem to be sustained by the current family structure and its community ecosystem. Important questions to answer in assessing these relationships include the following.

- To what elements of family structure—boundaries, hierarchy, alliances, coalitions—do occurrences of the presenting problem appear linked?
- What family functions are blocked by the problem? If not for the problem, what would be happening that is not happening now?
- For whom is the problem a concern? Who is most affected? Who would need to change for the symptom to disappear?

**What to Do.** Structural family therapists ameliorate symptoms by shifting family structure. Boundaries can be strengthened or weakened by behavioral assignments that
Strategic Family Therapy

Strategic therapy is built upon the premise that a therapist is responsible for planning a strategy that solves successfully the family’s presenting problem. The therapist sets clear goals that intervene by changing relational and communicational processes in the family (Madanes 1981, Stanton 1981). Strategic therapy was designed as a counterpoint to psychodynamic psychotherapy by emphasizing “how” people can behave differently in order to solve problems, rather than “why” they behave as they do. Its development was heavily informed by Ericksonian hypnotherapy and application of cybernetics principles to human systems (Madanes 1981). Its impetus also came from the discovery of the one-way mirror, permitting detailed tracking of repetitive family processes that triggered symptoms. Strategic therapy planned interventions that would disrupt such behavioral sequences, whether by direct behavioral prescriptions or by indirect paradoxical interventions.

What to Think About. The focus of strategic therapy is upon problem solving. Problems are viewed as persistent efforts by one or more family members to apply a solution that makes sense but is inadequate for the problem at hand, such that “the solution becomes the problem.” Common-sense understandings often lead people to pursue unsuccessful strategies even though it ought to be apparent that the problem is not resolving. For example, people intuitively attempt to cheer up a person who is depressed, even though cheering up (a solution) usually makes the depression (the problem) worse.

Strategic therapists commonly view clinical problems as emerging out of difficult life-cycle transitions, both predictable ones (e.g., marriage, birth of a child, separating/individuating of an adolescent) and unpredictable ones (e.g., loss of job, sudden illness, a death in the family) that necessitate shifting to new patterns of perceiving and acting. At such times when innovative problem solving is needed, people nevertheless persist with once successful strategies that are now outdated.

What to Look For. Strategic therapists are most interested in the here-and-now context of the problem, rather than in its history. They seek to learn what each involved person believes about the problem, and how these beliefs are acted upon in efforts to generate a solution. Questions are asked about who, what, when, where, and how people are involved, in order to ascertain how moves are sequenced in the family game.

What to Do. The central aim of a strategic therapist is to motivate family members to try novel solutions, rather than repeating what has been tried in the past. Psychoeducation, direct behavioral assignments, and paradoxical or defiance-based directives are the cornerstones of strategic therapy.

In-session interventions and out-of-session homework are used. Strategic therapists have become best known for their paradoxical directives. Paradoxical directives include the following.

• Reframing or relabeling the symptom. By changing the context of actions constituting the symptom, the meaning of the event is reframed. For example, a husband’s emotional distancing could be reframed as “his way of getting his wife to notice him.”

• Prescribing the symptom or behavioral sequence. By using a rationale that is plausible in its logic, a therapist can encourage family members to engage in the very behavior that needs to be eliminated. For example, a wife whose husband is emotionally distancing might be told to continue to pursue her husband because “this lets him know that he is the center of her life and that there is nothing else about her life that she finds valuable or interesting.” She might be instructed to continue in herbehavior for

Clinical Vignette 3

Before Roberta’s marriage to Bill, Roberta and David had lived together as a unit for years, which had fostered an intense bond between them. In order to shift successfully to the structure of a stepfamily, Roberta needed to let a relationship build between David and Bill, and that between her and David to loosen. She also needed to build a relationship with Bill’s son.

In their spousal relationship, both Bill and Roberta needed to enhance their sexual intimacy. They needed to develop a style of working together as a parent team. Bill, in addition, needed to limit appropriately his involvement with his ex-wife. Both boys needed to have time to create a relationship with each other.

In planning a strategy to counter fights around disciplining the two boys, the therapist began by viewing Roberta and David as an enmeshed-couple. That is, Roberta would “know” what David felt when Bill attempted to discipline him, so she stood up for David “to protect him.” Although she saw herself as a protective parent, she was not allowing Bill and David to work things out for themselves. Moreover, David learned how to provoke Bill in order to prompt his mother to side with him.

The therapist gave Bill and Roberta an assignment to go out to dinner in a quiet, comfortable restaurant and to make a list of David’s positive qualities and actions that they felt good about. They were then told to make a list of those behaviors, which they felt were destructive, and what they thought should be done about them. The therapist then met with Bill and Roberta alone and discussed their lists. As the therapist had anticipated, a fight ensued about David’s behavior in the subsequent family meeting with David present. Through this spontaneous enactment, the therapist helped the family rechoreograph the sequence of interactions. In a new pattern, the couple would first establish decisions together, then would support each other in avoiding David’s moves to side his mother against Bill.
his sake, even though it may give her friends a distorted idea about her. When the refraime “fits,” yet the new meaning feels distasteful, the rebound against the directive can paradoxically propel therapeutic change.

• Restraining the system. The therapist can attempt to discourage or even deny the possibility of change. For example, a therapist may tell couple partners to “go slow” or may emphasize dangers of improvement. Family members may then react against the therapist’s conservative outlook by pressing forward to change.

• Positioning. The therapist attempts to shift a problematic “position” (usually an assertion that the patient is making about self, the problem, or a partner) by accepting but exaggerating that position. This intervention is used when the partner's position is thought to be maintained by its complementary, reciprocal response from the other partner. For example, when one partner takes an optimistic stance and the other a pessimistic one, a therapist may suggest the pessimistic spouse to worry even more so that the optimistic spouse can feel more secure and even more happily optimistic. Here, too, if a new explanation has a plausible logic, but frames the behavior in a manner that renders it aversive, the behavior will change. A strategic therapist might have tracked the characteristic pattern of arguments between Bill and Roberta as given in Clinical Vignette 4.

Clinical Vignette 4

When Roberta felt unheard, she yelled louder. As her voice became louder, Bill became more emotionally distant and coldly rational. As the fight escalated, Roberta first threw an object at Bill, then asked him to leave, then threatened divorce. The strategic therapist considered each of these behaviors to be efforts at a solution that likely had worked successfully in past conflicts, but now, was amplifying the problem.

The therapist noted that each time the couple “made up” each reported having “the greatest sex.” She referred to their pattern as an “accordion dance” and told them that should they persist in it, they would in time reach a point of no-return. She then modified its rules by suggesting that Bill ask Roberta to leave the room to cool off when she appeared to be losing control. If Roberta refused to leave, then Bill would say that he needed to take a walk to clear his head.

Alternatively, the therapist might have suggested to Roberta that “if you don’t want to be heard, then you should continue to scream louder … but if you do want Bill to hear you, then you should do an ’EF Hutton,’ that is, to whisper instead of yell.”

Cognitive–Behavioral Family Therapy

Cognitive–behavioral family therapy applies principles of learning theory to help family members solve problems by modifying cognitive distortions and repetitive problematic interactions, and by learning new knowledge and skills. Cognitive–behavioral family therapy relies heavily upon family psychoeducation and a teaching/coaching stance of the therapist.

Behavioral family therapy emerged from behavioral modification programs for young children with such problems as bedtime tantrums, nocturnal enuresis, and aggressive behavior (Arias 1992, Falloon 1991). It is based upon the influence family members hold by offering positive and negative reinforcements to other family members. Parents and spouses are trained to eliminate reinforcement contingencies for undesirable behaviors.

Cognitive interventions engage family members as coinvestigators who study the ecology of family problems and symptoms and discern how thoughts, feelings, and behaviors interplay. A therapist assists family members in identifying when such cognitive distortions as catastrophic thinking, overgeneralization, or misattributions lead to conflicts in relationships (Epstein et al. 1988, Freeman et al. 1989) (see Clinical Vignette 5).

Clinical Vignette 5

Addressing David’s attention-deficit disorder was an important aspect of the therapy, and Bill and Roberta began reading materials about the disorder. In sessions, they were taught to make distinctions in David’s behavior according to Green’s (2000) concept of three baskets. In Basket A steps relevant to safety that must be taken regardless whether the child becomes agitated in response; in Basket B are new skills to be taught and practiced, pacing the teaching according to the child’s capacity to respond; in Basket C are the child’s behaviors that should be ignored. During the family sessions the therapist worked on problem-solving techniques and empathic listening, helping family members to notice and comment on positive feelings and to speak negative feelings respectfully.

What to Look For. Families presenting problems for therapy often have

• difficulties in recognizing deviant behavior
• lack of clearly-defined family rules
• problems in emotional communication among family members, usually a paucity of expression of positive feelings coupled with an excess of negative expressions
• relational conflict associated with either a paucity of relational skills or interpretive errors based on faulty assumptions or cognitive distortions.

What to Think About. A cognitive–behavioral family therapist considers each member of the family to be doing his or her best to cope with the behavioral contingencies perceived at that point in time, given the practical and emotional restraints experienced. Family members need to acquire knowledge about cognitive and behavioral principles, to gain skills needed to reinforce desired behaviors, to eliminate reinforcement of undesired behaviors, to modify faulty assumptions and interpretations of others’ actions, and to learn skills for communicating clearly and effectively.

What to Do

• Psychoeducation. Educational modules about the presenting problem are taught when family members appear to lack a significant understanding of issues, ranging from such general topics as developmental milestones of children and principles of learning theory, to specific
organized family dialogues that were tailored to be protective, inclusive, and responsive to each family member. The therapist would then step back from an authoritative stance as expert so that this empowered dialogue itself could originate solutions.

The postmodern therapies have made contributions that have broadly influenced family therapy through the following methods.

- Methods for crafting questions that maximize reflection and creative problem solving.
- A persistent focus upon family strengths, skills, competencies, resources, and other sources of resilience.
- Clinical methods that counter adverse cultural influences that help generate and maintain family problems.

Narrative and feminist therapists encourage family members to become mindful how narratives from the broader culture constrain their lives. Solution-focused therapists examine how people construct solutions to problems in daily life. They help family members learn from those occasions when the problem is not occurring and to learn from those “exceptions” when the problem might have been expected to occur but did not. By studying occasions when the problem did not happen, family members can practice tasks that amplify the frequency and intensity of these “solution sequences.”

While postmodern family therapies have reoriented family therapy toward family resilience, empowerment, and strategies to counter cultural oppression, they also have continued to utilize techniques and methods from other therapeutic traditions as needed to solve particular problems. For example, a feminist family therapist might well work with a couple on gendered marital roles that have contributing to the wife’s depression. At the same time, she might work in the manner of a structural family therapist in facilitating an alliance between parents to communicate clearly to their child and to provide consistent behavioral consequences for their child’s temper tantrums.

What to Think About. Each person makes sense out of his or her life experiences by attributing meaning to them. This meaning is shaped by a canon of personal narratives that are told and retold to self and others. Among the most important are those of identity about who one is as a person and to whom one belongs as a family. Certain dominant narratives play a larger role than other narratives in organizing perceptions, thoughts, and actions. How a family member views oneself and other family members is shaped by the limits of available language for articulating experience—the metaphors, stories, and beliefs that he or she employs. Relational impasses occur and problems emerge when

- one or more family members lack either the emotional vocabulary or narrative skills necessary for making one’s personal experiences understandable to others;
- available narratives preclude any ways of relating other than conflictual ones;
- specific words hold very different meanings for different family members due to unique personal stories connected to that language (e.g., “loyalty,” “trust,” “safety”);
family members have become positioned relationally such that they cannot hear, tell, and/or expand their stories in conversation. They have become so confused by or habituated to the conflict that they have stopped listening.

Therapy can provide a context in which family narratives that limit relationships can be identified. Effects of constraining narratives can be attenuated when specific historical, cultural, or political contexts out of which they emerged are discussed, and the interpretive assumptions upon which they rest are made explicit. Alternatively, more useful narratives can be identified that have gone unnoticed within forgotten experiences family members have had with each another.

What to Look For

- Listen for the specific words and precise manner in which people use language. A focus of therapy is the language itself and the limited possibilities it entails.
- Metaphors, oft repeated phrases, and other evocative uses of language are noted as “doors to be knocked upon” by asking specific questions about family members’ stories of lived experiences that gave them meaning.
- “Unique outcomes” or “exceptions” when problems might have been expected to occur, but did not.

What to Do. Narrative approach to therapy consists of two phases—first, eliciting family narratives that have been important in their influence upon family life; second, authoring new narratives and reauthoring old ones that have been too limiting in their possibilities.

- Eliciting important narratives. First priority is creation of a therapeutic relationship within which important first-person narratives can be safely told, acknowledged, and understood. In particular, the therapist carefully watches for nonverbal signs that the dialogue is opening up or shutting down as indicated by family members’ breathing, posture, and flow and tone of speech.
- Authoring new narratives and reauthoring constraining ones. As narratives relevant to the problem are told, the therapist crafts questions that facilitate:

(a) Retrieval of other forgotten, or unnoticed, narratives that might enhance solving the problem of the therapy, in contrast to a narrative that has been dominant. For example, an elderly husband might be asked: “In what year of your life were at the top of your game? What was happening then in your life?” Such a question conceivably might bring forth stories of vitality about this elderly man’s preferred identity that had been forgotten in the present era of his life, with its frail health, depressed mood, and conflicted marriage.

(b) Asking questions about details of a constraining narrative that shift its meaning through expanding awareness of its historical contexts; punctuating differently its time-line; adding forgotten characters whose actions had also contributed to the story; heightening awareness of complexities in characters’ states of mind.

- The therapist employs such questions as circular, reflexive, unique outcome, or relative influence questions (Tomm 1987, White 1989) to gather fresh descriptions of family life that might constitute an alternative, preferred narrative. For example, a unique outcome question such as “Have there been occasions when you had every reason to expect your son to disobey the rules, but to your surprise he did not?” can elicit new accounts of a son who at times can exercise judgment and self-control, rather than a pervasive narrative of “conduct disorder.” Likewise, such a relative influence question as [to the son] “When you and your mother spend the day together, how many times out of 10 does ‘disobedience’ take charge of you? How many times out of 10 do you take charge of ‘disobedience’?” can open a path to a treatment plan in which the son joins an effort to increase from 3 to 4 the number of times out of 10 then he takes charge of disobedience.

- A solution-focused therapist may assign family members the task of studying segments of time when the problem is not occurring, looking for exceptions. Examples of solution-focused questions include

(a) Between now and the next time we meet, I want you to observe what happens between both of you that you do value, would NOT want to change, and would like to see happen more often in the future.”

(b) The miracle question (de Shazer 1985) — “Suppose that one night, while you were asleep, there was a miracle and this problem was solved. How would you know? What would be different? How would other family members know without you even saying a word about it?” [The therapist then negotiates with family members what part of this new reality that they would be willing to implement the next day, as if the miracle had occurred.]

(c) (Weiner-Davis 1992) “If the problems between you and your partner got resolved all of a sudden, what would you do with the time and energy you have been spending on fixing or worrying about the marriage? Describe what you would do instead.”

(d) (Weiner-Davis 1992) “What might be one or two small things that you can do this week that will take you one step closer to your goal?”

(e) (Weiner-Davis 1992) “What, if anything, might present a challenge to your taking these steps this week, and how will you meet the challenge?”

Some interviewing methods associated with the postmodern therapies are illustrated in Clinical Vignette 6:

Clinical Vignette 6

Roberta repeatedly referred to her anger as a “flash flood.” Noting her selection of this metaphor, the therapist asks what important stories of her life experience gave special meaning to “flash flood.” She described growing up in the Southwest where in the middle of an arid summer, a thunderstorm could trigger a flash flood that suddenly and without warning swept away everything in its path. Later during a couple’s session with Bill present, the therapist asked Roberta: “Were there times when, to your surprise, you felt the thunder and lightening of your emotion, but instead of overflowing the river ran smoothly?” Roberta...
responded with an account of a time when she suddenly felt angry with Bill, but had “used words instead of action” and said, “I am mad.” The therapist then asked more detailed questions about what each of them noticed, thought, felt, and enacted on this occasion that had been different. She then said to Roberta, “Between now and the next time that we meet, I would like you to observe those times when your emotions begin to churn but you are able to ride the rough waters to a successful conclusion.” She then instructed Bill to notice those times when he would have expected Roberta to “blow up,” but she didn’t … and to notice what happened and how each of them felt at the time. In subsequent sessions a new plan for engaging in conflict was constructed out of their observations and reflections on this “unique outcome.”

From Family Therapy to Family Psychiatry

Family therapy through its early years treated families while often minimizing any need for psychiatric treatment of patients as individuals. The earliest approaches to family therapy built upon psychodynamic theory and extended to the family similar ideas about “family pathology” instead of psychopathology. Early versions of psychodynamic, structural, strategic, and cognitive–behavioral family therapies each sought to treat family pathology as the primary source of mental illnesses. By the late 1990s, however, family therapies were becoming more measured in their curative claims. They shifted to more collaborative stance in which families were regarded as allies in treatment, rather than sources of pathology. A new focus was placed on educating families about mental illnesses and their treatments, including pharmacological treatment for severe symptoms (Berman and Heru 2005).

Meanwhile psychiatry as a discipline was showing a renewed interest in roles of families in psychiatric treatment. Clinical research produced vulnerability/stress models for psychiatric illnesses that pointed consistently to both biological factors and family factors in the genesis and maintenance of mental illnesses. American Psychiatric Association Practices Guidelines for most psychiatric illnesses mandated attention to families (Berman and Heru 2005). Although seldom conducting formal family therapies, psychiatrists utilized family therapy skills when treating individual patients and in clinical work involving larger systems (Guttmann et al. 1999, Slovik et al. 1997).

Family psychiatry that has emerged since 2000 has emphasized family skills for assessment, education, and intervention as essential components of biopsychosocial treatment for individual patients. These family skills have focused on involvement of family members as collaborators in treatment, education of family members about medical, psychosocial and behavioral issues, interventions to reduce the burden of illness upon families, and mobilization of family strengths as resilience factors for preventing illness progression or relapse (Berman et al. 2006, Berman and Heru 2005, Heru 2006).

Family Psychoeducation

Family psychoeducation is a program of cognitive, behavioral, educational, and supportive interventions implemented in close consultation and partnership with family members. Family psychoeducation for schizophrenia best illustrates the evolution from pathology-focused family therapy to family-centered treatment that engages family members as collaborators. Early family therapists had hoped that a family approach would open new venues for treating schizophrenia where both psychoanalysis and the then available psychopharmacology had faltered. The Bateson project in Palo Alto made famous the double-bind theory of schizophrenia, concluding from analyses of audiotaped family conversations that psychosis was a coherent response to communications with conflicting directives between the explicit verbal message and the implicit nonverbal one (Sluzki and Vernon 1971). Subsequently, Jay Haley, a Bateson research team member, tailored family interventions around a Hamlet-like assumption that psychotic behavior represented a move by the psychotic family member to wield power through force of illness (Haley 1976, 1980).

These family therapy models that located the genesis of schizophrenia in family relationships and communications never gained strong support from empirical research. Moreover, family advocates were alienated by the implicit pathologizing of families with psychotic members. By the 1980s, some family therapists working with these disorders were proposing that family therapy could be more effectively applied by engaging families as partners in treatment, instead as sources of psychopathology. These efforts were characterized by a fresh set of assumptions (Dixon and Lehman 1995).

- Severe psychiatric disorders, such as schizophrenia and bipolar disorder, are regarded as illnesses.
- The family environment does not cause the disorder but can influence its course and severity.
- Support is provided to families who are enlisted as partners and collaborators in treatment.
- Family interventions are only one component in a treatment program that includes routine drug treatment and outpatient clinical management.

These new clinical approaches integrated psychoeducation, behavioral problem-solving training, family support, and crisis management in interventions with either individual families or groups of families.

The construct of expressed emotion (EE) played a significant role in the evolution of family psychoeducation (Anderson et al. 1986, Leff and Vaughn 1985). During a structured interview, families were given an EE rating based on observations of critical comments, hostility, and over-involvement among family members. Over two decades an enormous body of research suggested that patients living with families characterized by high levels of EE were more vulnerable to relapse (Bebbington and Kuipers 1994). Interventions were then designed that relied heavily upon family psychoeducation in order to help high EE families to change to a low EE status.

Development of family psychoeducation was also propelled by the self-help family education movement that emerged after the Reagan assassination attempt by a man with schizophrenia. Families mobilized by the National Alliance Against Mental Illnesses and related advocacy organizations demanded information that would help families...
cope with severe mental illnesses. Family psychoeducation approaches emerged that sought to "put the illness in its place" (Gonzalez et al. 1989) by helping families acquire the knowledge, skills, and resources needed to minimize the loss of time, money, and energy from a chronic medical or psychiatric disorder. These approaches avoided promising a cure. Rather, treatment was considered successful when family members accepted the presence of the illness but refused for it to organize the life of the family. Unlike earlier family therapies that avoided psychopharmacology, family psychoeducation approaches made maximal use of psychotropic medications to control disruptive symptoms and openly embraced interventions drawn from other individual, family, or social network therapies.

Family psychoeducation for schizophrenia was honed into a systematic therapeutic approach by well-conducted empirical research programs during the 1970s and 1980s and validated by empirical research studies (Goldstein et al. 1978, Leff et al. 1982, Hogarty et al. 1986). For example, the University of Pittsburgh Schizophrenia Research Project, by using intramuscular depot antipsychotic medications, determined that the benchmark relapse rate for psychosis in schizophrenia was 40–50% over a 2-year period, even with optimal adherence to medication treatment, and that rates were still higher among patients with multiple past relapses (Hogarty et al. 1986). They designed a family psychoeducation program in which family alliance-building and education about the illness began before hospital discharge. Groups of families were gathered for a “survival skills workshop” consisting of discussions about schizophrenia diagnosis, etiology, use of antipsychotic medication, and the needs of patients and family members when there is a psychotic member. They made practical suggestions for adjusting performance expectations, diminishing high expressed emotion, simplifying family communications, normalizing family routines, and making best use of professionals. Subsequent family meetings after discharge then addressed both adherence to antipsychotic medications and family psychosocial processes in a phased plan covering the first-year “reentry phase,” social and occupational rehabilitation, and latter stages of treatment. Family meetings focused particularly upon elements of schizophrenia for which therapeutic responses by family members would be often counterintuitive—the need to soften criticism and lessen expectations for high performance because of vulnerability to emotional overstimulation and confusion from negative symptoms of schizophrenia (apathy, isolation, amotivation) are considered to be symptoms of the illness rather than laziness or a flawed character.

The subsequent treatment outcomes were impressive. The first-year relapse rate dropped from the expected 50%, with antipsychotic medications alone, to 19% when family psychoeducation was added, and to 0% when medications, family psychoeducation, and social skills training for the patient were combined.

The effectiveness of family psychoeducation was shown to be further amplified when applied to family groups, rather than to individual families in isolation. Single-family therapies often involve only 2 or 3 people, while a multifamily group commonly involves 10 or more people. Multifamily groups thus expand the patient’s and family’s social network (McFarlane 2002). Their usefulness has been demonstrated not only for psychiatric, but also for nonpsychiatric disabling medical conditions (Gonzalez et al. 1989, Steinglass 1998).

For schizophrenia, William McFarlane and colleagues designed a multifamily group therapy that has shown particularly robust therapeutic effects in empirical studies (McFarlane 2002, McFarlane et al. 1995, 1996). A group of families meets regularly to work toward creating home and social environments in which affects would be relatively warm, communications clear and simple, change kept to a minimum, the impact of life events cushioned, and graduated expectations set at a level consistent with the patient’s state of symptoms. In an initial workshop, patients do not join other family members during the initial orientation and educational sessions, but do join them for later illness management sessions. Each multifamily group meets biweekly, led by two cotherapists and including patients. An individual patient’s or family’s problem is addressed by the entire multifamily group in a structured, problem-solving process guided by the clinician. These family meetings focus upon management issues for different symptoms and families’ uncertainties about how best to promote recovery and rehabilitation. After the second year, the ongoing groups typically evolve into natural social networks for mutual support in enhancing rehabilitation and quality of life. McFarlane’s multifamily group treatment, which included family psychoeducation and maintenance antipsychotic medications, reduced risk of relapse for an extended period of time and did so more effectively than family psychoeducation with individual families. Elements that appeared to be tied to its outcome effectiveness included:

- creation of social contacts and support;
- problem solving with others bearing the burden of the same disorder;
- countering stigma;
- cross-parenting of adolescents;
- normalizing family communications;
- intervening effectively during crises.

In a cost-saving estimate, the multifamily psychoeducational groups achieved a 1:16.50 ratio, saving $16.50 for every dollar spent on mental health services.

Family-focused psychoeducational interventions have been developed for other psychiatric disorders. Family-focused treatment for bipolar disorder, for example, integrates family psychoeducation, communication training, and problem solving into a 20-session therapy extending over most of a year. This intervention in a controlled study has been shown to delay relapse of bipolar disorder (Miklowitz and Goldstein 1997, Miklowitz et al. 2000).

**Family Resilience**

While family psychoeducation approaches have focused on roles that families can play in reducing frequency of illness relapse or buffering its severity, family resilience interventions extend this strategy to identify salutary family processes that not only buffer severity of illness, but prevent its onset for those at risk. Key processes can be identified that enable couples and families facing disruptive crises or persistent stresses to strengthen relationships, regain functioning, and further the growth of its individual members (Walsh 1998, Wolin and Wolin 1993). For example, twin studies of schizophrenia have identified some families who...
seemed capable of reducing the risk of illness onset for genetically at-risk adopted children. In addition, some children exposed to horrific childhood experiences with alcoholism, mentally ill parents, physical abuse, sexual abuse, or emotional deprivation, nevertheless have grown up to be psychologically healthy and hardy adults. Michael Rutter’s (1985, 1987) research found that even combinations of severe risk factors were predictive of mental illness for no more than half the affected children.

Family resilience refers to coping and adaptational processes in the family as a functional unit (Walsh 1998, Wolin and Wolin 1993). From this perspective, a stressor affects at-risk children only to the extent that they disrupt crucial family processes that otherwise would neutralize or buffer the stressor (Patterson 1983). Family resilience rests upon several systemic principles (Walsh 1998, p. 24).

- The hardness of individuals is best understood and fostered in the context of the family and larger social world, as a mutual interaction of individual, family, and environmental processes.
- Crisis events and persistent stresses affect the entire family, posing risks not only for individual dysfunction but also for relational conflict and family breakdown.
- Family processes mediate the impact of stress on all members and their relationships, with protective processes fostering resilience by buffering stress and promoting recovery, and maladaptive responses heightening vulnerability and risks for individual and relationship distress.
- All families have the potential for resilience, which can be maximized by encouraging their best efforts and strengthening key processes.

Innovative research programs during the 1980s and 1990s sought to identify family factors contributing to the resilience of at-risk children and to design interventions that could help families better protect vulnerable children. These family resilience programs regarded resilience not to be embedded within the character of the person, but imminent within the communicational and relational systems of the person’s family and social networks.

The family resilience program best validated by empirical research has been the family-based program of William Beardslee and colleagues at Boston Children’s Hospital to reduce risk of onset of depression for children reared by a parent with a major depressive disorder. Epidemiological studies have established that children growing up in a home with a depressed parent have a 50% likelihood of developing a depressive disorder during adolescence and a four- to six-fold greater likelihood of receiving a psychiatric diagnosis in adulthood, particularly a depression diagnosis, than children growing up in a home with neither parent depressed (Beardslee 1998, Beardslee et al. 1998, 1999). Beardslee’s group studied children who ultimately showed no signs of adult life depression, despite growing up with a depressed parent, in order to identify individual and family processes that could attenuate this risk. Factors conferring protection upon children at risk for depression were identified as

- developing deep commitments to and involvement in interpersonal relationships;
- seeking self-understanding as a way to deal with a parent’s depression;
- expressing articulate understanding of the parent’s illness and problems ensuing from it;
- refusing to feel blame or guilt for the parent’s illness.

Beardslee and colleagues designed a family-based cognitive–behavioral intervention that attempted to educate families about depression, using either a clinician’s visit or group lecture as format. The intervention sought to enhance the understanding of depression in all family members and to promote resilience in children at risk. Its steps consisted of an initial assessment of all family members. A program of psychoeducational material about affective disorders not only taught facts but linked the educational material to that family’s life experiences. Family members were counseled to counter children’s feelings of guilt and blame. Children were encouraged to develop relationships both within and outside the family. Parents were encouraged to facilitate their children’s independent functioning in school and outside home (Beardslee 1998). This clinician-facilitated format was conducted over four to eight sessions, initially alone with parents then individually with the children, ending with a whole family session and a wrap-up session. Follow-up studies have validated sustained reduction in family risk factors for depression three years after intervention including an improved understanding of the parent’s illness by the child; better communication between parents and children about the illness; and enhanced attunement of parents to their child’s experience; and higher adaptive functioning by the child. Children who began showing symptoms of depression were identified early in the course and treated (Beardslee et al. 1999). Two notable processes that appeared correlated with effectiveness of the intervention were

1. active linking of life experiences of the family to information presented, rather than simply delivering factual information;
2. giving the child an active voice in family discussions about the illness.

With programs such as Beardslee’s, family resilience programs have moved past treatment of acute illness and relapse prevention, to primary prevention of the disorder itself. Such programs identify risk factors and protective factors for onset of illness, relate these factors to family organization, communications, and knowledge of the disorder; and design family interventions that enhance family understanding, attenuate risk factors, and amplify protective factors (see Table 92–1).

Reducing Caregiver Burden in Chronic Disorders

Family interventions have helped relieve suffering of family members who care for patients with chronic illnesses. Family members of patients with chronic disorders, both medical and psychiatric, suffer financial difficulties, limited social lives, loss of recreation, and constant worry and vigilance. Family members in turn impact both the psychological well-being and capacity for disease management by the
ill family member. Objective burden describes the effects of caregiving on health, activities, and finances of caregivers, while subjective burden consists of anxiety, depression, and psychosomatic symptoms associated with the caregiving role (Heru et al. 2005).

Caregiver burden reduction strategies have most commonly targeted dementias and such commonly occurring diseases as cancer and heart diseases. A metaanalysis of 70 research studies found that family interventions including only spouses successfully reduced patient’s depressive symptoms. Further, interventions including other family member reduced depressive symptoms among the caregivers (Martire et al. 2004). The Resources for Enhancing Alzheimer’s Caregiver Health (REACH) has served as a research program for developing multimodality strategies to reduce family burden in Alzheimer’s Disease, emphasizing family psychoeducation and behavioral problem-solving skills (Gitlin et al. 2003, Teri et al. 2005). Caregiver burden reduction programs have similarly been developed for chronic pain, heart disease, cancer, end-stage renal disease, and other chronic physical disorders.

Schizophrenia has been found to produce as great an objective family burden as does severe physical disease. However, its subjective burden is even greater due to the impact of the psychosis upon family members, including the perceived lack of patient contributions to family well-being, rejection of the patient by relatives, more limited social networks, and family worry over suicidal ideation (McDonell et al. 2003, Mueser et al. 2001, Perlick et al. 2006). Significant improvement in family burden in families with schizophrenia has been demonstrated in a controlled study utilizing a psychoeducation family intervention. This family intervention educated family members about symptoms, treatment, and early signs of relapse; provided communication skills training; and provided problem-solving skills training (Magliano et al. 2006). Childhood autism produces a high level of family burden, similar to that of schizophrenia (Hastings et al. 2005). Family psychoeducation has been found to reduce family burden for caregivers of patients with chronic mood disorders (Heru et al. 2005).

### Family-Centered Treatment in International Mental Health

The extent to which North America values differentiation by individuals has arguably made it a less favorable climate for family-focused approaches than other cultures of the world. High divorce rates, fluid urban lifestyles, and frequent geographic relocations, all served to weaken the bonds of both nuclear and extended families during the latter half of the 20th century. Although couples therapy is firmly established in the American mental health system, family therapy has remained marginal.

People worldwide, however, both in their local cultures and in American immigrant groups are far more based within their families. In many world cultures, a person is more a family member than an individual, psychologically as well as in commitments of time and personal resources. Consequently, family-centered therapies are often more fitting for non-Western cultures than the individual psychotherapies developed in North America and Western Europe (Weine et al. 2004). Moreover, family-centered approaches hold an advantage in resource utilization in many countries where there are few mental health professionals and little funding of mental health programs for large, poor populations (Baron 2002, Baron et al. 2002). Treating non-Western patients as individuals outside their family and community contexts has been described as the most common cross-cultural error among psychotherapists (Elissas 1997, p. 118).

Family-centered treatment can serve as a point at which Western psychological methods and local culture can meet on more equal footing than in individual psychotherapies. Rebuilding family and social networks after migration is vital to successful adaptation in a new land (Shuzki 1992, 1998). Culturally sensitive family therapy focuses upon the problems of a family in transition between old and new cultures. It rests upon negotiation and collaboration and the capacity of a therapist to hold multiple perspectives simultaneously, moving back and forth between the family culture “insider” view and the “outsider” Western psychiatric view of a clinical problem. Such family therapy utilizes family meetings to create a context in which family predicaments can be presented through the narratives of everyday family life, while interweaving clinical methods for working with and making sense of these stories in their cultural contexts (DiNicola 1997).

Family-centered community mental health services has emerged as an organizing principle for mental health recovery programs in refugee communities and post-war settings following the campaigns of genocide, ethnic violence, and civil warfare of last quarter of the 20th century (Baron 2002, Baron et al. 2002, Weine et al. 2003). The Kosovar Family Professional Educational Collaborative (KFPEC) is an example of a successful family-centered approach toward community mental health services in Kosovo, a country with many mental health needs but few available funds or trained mental health professionals (Griffith 2002, Griffith et al. 2001, Weine et al. 2003). The KFPEC incorporated the strengths of family psychoeducation and family resilience-building programs discussed above, in a collaboration with Kosovar mental health professionals to train Kosovar clinicians in family therapy skills and to organize mental health services around the strengths and needs of Kosovar families.
Kosovo, a Kentucky-size country of two million, was left after the 1999 war with only five psychiatrists, two psychologists, no psychiatric social workers or nurses, and no hospital for the chronically mentally ill. In recognition of the extended family as the core unit of Kosovar society, the KFPEC was established to link the University of Prishtina School of Medicine with American universities and professional organizations (Griffith et al. 2001, Griffith 2002). The KFPEC has supported development of a family-focused community mental health system by training clinicians and developing services fitted to the strengths, skills, and traditions of Kosovar families. The following vignette illustrates the application of this family resilience approach with a traditional Kosovar family who were coping with the loss of five family members from the violence of the war:

The T family was engaged as the primary unit of therapy by the University of Prishtina clinicians. They met with T family members in their family home, drawing upon family and cultural traditions, and helping them adapt where flexibility and innovation were needed. Kosovar families particularly in villages and rural areas, are distinguished by a well-defined hierarchy of authority and clearly specified roles for each family member, determined largely by age and gender. Loyalty among family members is intense. Decisions about work, marriage, and the handling of money are all made in the context of what is best for the family as a whole. Amplifying these family strengths in recovery from trauma was an approach that can be contrasted with one more commonly employed in North America, in which individuals are screened for posttraumatic symptoms and then treated in professional offices.

**Summary**

Family therapy has evolved from a treatment modality that searched family relationships for the causes of mental illness to a framework for engaging the strengths and competencies of families in solving clinical problems and treating psychiatric disorders. The various clinical traditions of family that matured during the 1960s and 1970s remain rich sources of ideas and interventions that can be integrated into multimodality programs alongside family psychoeducation, individual psychotherapy, and psychopharmacology. Such family-centered approaches as multifamily psychoeducation groups are sufficiently supported by empirical research to be regarded as evidenced-based practices. Family-centered models for primary prevention of major psychiatric disorders and family-centered community mental health programs for immigrant, refugee, and international populations represent the developing frontiers of family therapy.

**Appendix I: Psychodynamic Family Therapy**

**What to Look For**

- Projective identification.
- Unresolved grief.
- Clarity of ego boundaries and capacity for intimacy/separateness.

**What to Think About**

- Internal processes within individual family members shape family interactions.
- Family members’ motivations, conflicts, defenses, and relationships from the past, currently influence present relationships.
- Therapeutic change occurs through family members gaining conscious insight into previously unconscious processes generating problems in family relationships.

**What to Do**

- Opening emotional expression in family relationships.
- Clarifying communications.
- Encouraging family members to speak from the “I” position.
- Interpretation of unconscious conflicts to resolve projective processes, cutoff relationships, and difficulties in modulating closeness and distance in family relationships.
- Psychodramatic techniques, such as doubling and role reversal.
- Therapeutic rituals to facilitate developmental transitions and grief over losses.
- Family genograms.

**Structural Family Therapy**

**What to Look For**

Contrasting the particular family structure with that “normal” to the culture and developmental stage in terms of the following.
Organization (structure)
Rules (sequences of action)
Roles that shape family members’ actions
Boundaries
Hierarchy of power
Alliances
Coalitions
Verbal and nonverbal behavioral sequences.

What to Think About
Presenting problem results from a family structure out of alignment with the culture and the developmental stage of the family.

What to Do
• Actively shift the family structure
• In-session enactments
• Out-of-session homework assignments

Strategic Family Therapy
What to Look For
• Here-and-now context of the problem.
• Who, what, when, where, and how people are involved in trying to solve the problem.

What to Think About
• “The solution to the problem is the problem.”
• Difficult life-cycle transitions give birth to clinical problems when people persist in old coping strategies but relational and communication processes need to change to meet new life contexts.

What to Do
• Psychoeducation.
• Direct behavioral assignments to adopt new problem-solving strategies.
• Defiance-based, paradoxical interventions.

Cognitive–Behavioral Family Therapy
What to Look For
• Family member difficulties in recognizing deviant behavior.
• Lack of clearly defined family rules.
• Problems in emotional communication among family members, usually a paucity of expression of positive feelings coupled with an excess of negative expressions.
• Relational conflict due to a paucity of relational skills.
• Relational conflict due to interpretive errors based on faulty assumptions or cognitive distortions.

What to Think About
• Each member of the family is assumed to be doing his or her best to cope with the behavioral contingencies perceived at that point in time, given the practical and emotional restraints experienced.
• Family members need to learn cognitive and behavioral principles of learning.
• Family members need to gain skills needed:
  1. To reinforce desired behaviors;
  2. To eliminate reinforcement of undesired behaviors;
  3. To modify faulty assumptions and interpretations about other family member’s actions;
  4. To learn skills for communicating clearly and effectively.

What to Do
• Conduct psychoeducation about the presenting problem.
• Conduct skill training in empathic listening expressing positive feelings, and speaking negative communications respectfully.
• Conduct training in problem-solving and conflict-resolution skills.
• Teach operant conditioning strategies for behavior shaping with children.
• Teach principles for contingency contracting to replace coercive and blaming behaviors with contracts specifying what each family members agrees to perform.
• Teach family members to utilize behavioral observation and thought diaries in out-of-session assignments to track patterns of thoughts, feelings, and behaviors that generate symptoms.

Postmodern Family Therapies
What to Look For
• Listen for exact usage of language expressed as metaphors, stories, and beliefs.
• Listen for first-person narratives from family members’ lived-experiences that imbue with meaning such abstractions as “love,” “trust,” and other important language of relationships.
• Note exceptions, or unique outcomes, when problems might have occurred but surprisingly did not.
• Note what is happening at times when problems are absent.

What to Think About
• The limits of a person’s language constitutes the limits of his or her experiential world.
• Narratives, or stories, are the basic units of human experience.
• A canon of personal narratives shapes the meaning each family attributes to his or her experience.
• Narratives of identity, about who one is as a family member, and who we are as a family, strongly influence family interactions.
• Family conflicts emerge:
  1. when lack of narrative skills makes their experiences unintelligible to others;
  2. when the available narratives preclude ways of relating other than conflictual ones;
  3. when specific words or expressions hold very different meanings for different family members due to the personal narratives with which they are associated;
  4. when family members become positioned relationally such that they cannot hear, tell, and/or expand their stories in conversation.

What to Do
• Focus on creating a dialogue in which important personal narratives can be safely expressed, heard, and reflected upon by family members.
• Ask questions that elicit forgotten, or unnoticed, narratives of family life that open better possibilities for solving problems than the current narratives that have dominated the family dialogue.
• Engage family members in an inquiry of
  1. what is happening in family interactions when problems are being solved successfully and symptoms are not occurring;
  2. skills, practical knowledge, competencies, and resources of the family that can be brought to bear upon the problem.

Introduction
Humans as a species are hardwired to form romantic attachments for the purposes of emotional connection and security and raising the next generation. Culture dictates the ways in which these biologically based needs are structured. For example, in some cultures primary attachments remain within the family of origin and marriage is more of a business institution; in cultures with arranged marriages love is assumed to develop after the wedding, not to be its cause. In Western industrialized society in the last decades, several notable trends have emerged:

- Decreasing rates of marriage and increasing rates of alternative forms of couples and families, including long term cohabiting unmarried couples, gay and lesbian partnerships, long term monogamous couples not living together, and serial monogamy with complex stepfamily forms.
- An ongoing and consistent, if not universal, move toward more gender equality in marriage. In the majority of these marriages, both partners work and share child care. (Less than 10% of marriages in America consist of a working father, stay at home mother and children under 18 and most of those women will eventually enter the workforce at some point in their lives.) This pattern is complicated by the needs of children, which still fall disproportionately, on women, and by men's greater earning power.
- An increasing assumption that a marriage should fill deep emotional needs for intimacy and friendship and if it does not, it should probably end. In previous years, it was assumed that the needs of the family and community should outweigh, to some extent, one's personal needs.
- Greatly increased life expectancy and increased health in the later years. This has lead to longer post-childrearing stages of life, and also to somewhat increased later life divorces and remarriages as people contemplate more years to explore and develop themselves.

- What has stayed the same is the wish for a sense of trust and emotional security; the possibility of romantic love, which can develop at any age, and the need to have a few consistent adults present to take care of children's attachment needs during the childrearing years.

The couples therapist of this decade must have a sense that there are many ways to do “family,” but that attachment needs, in and of themselves, are very powerful. Social neuroscience research demonstrates the biological basis of attachment, its power and the dysregulation and grief consequent to its loss. Couple relationships are a true example of biopsychosocial structures.

Definition: What Is “Couples Therapy?”
Marital or couples therapy can be defined as a format of intervention involving both members of a dyad in which the focus of intervention is the problematic interactional patterns of the couple. In this chapter, we will use marital and couples therapy interchangeably as the majority of the issues are the same. The focus of couples therapy is on the dyad and its intimate emotional and sexual aspects.

Currently, there are various models and strategies for treating couples, as described in the chapter on Family Therapy. Each may emphasize different assumptions and types of interventions. Some therapists prefer to operate with one strategy in most cases, whereas others combine these strategies, depending on the presenting problem and the phase of treatment. Whether a therapist specializes in one or another approach, or is eclectic, some hypotheses will be formed about the nature of the couple's difficulty and the preferable approach to adopt.

Some therapists emphasize reconstruction of past events, whereas others choose to deal only with current behavior as manifested during the therapy session. Some therapists favor verbal exploration and interpretation, whereas others are more in favor of utilizing an action or experiential mode of treatment, either in the session itself
or by requiring new behavior outside the interview. Some therapists think in terms of problems and symptoms and attempt to decode or understand possible symbolic meanings of symptomatology, whereas other therapists focus on the potentials for growth and differentiation that are not being fulfilled. One new method, not mentioned in the chapter of the previous edition, is Emotionally Focused Therapy, (Johnson and Whiffen 2003), which explicitly uses the new research on attachment as its base and is a well researched model. Some therapists utilize one or a very limited number of methods in dealing with a whole range of “problems,” but others are more eclectic and attempt to tailor the treatment techniques to what they consider the specific requirements of the situation.

In our experience in training and working with various therapists, it seems they choose one school or another based on their training and or their personality style. For example, a therapist who has had psychoanalytic training would frequently choose to employ psychodynamic techniques when working with couples. For example, a very directive person would probably prefer cognitive–behavioral methods, while a person who prefers long-term emotional intensity over problem solving might gravitate to experiential models. Individuals and families as well may prefer some ways of working over others. This chapter encourages the integration of a variety of techniques depending on the particular problem and personalities of the couple as well as the skill-set of the therapist. It also encourages the therapist to look beyond the problem at hand, that is, the presenting complaint, to issues of power, intimacy, and personal growth. Our approach is to emphasize models that have (at least some) empirical data.

With the therapeutic focus on one person, the emphasis is often on the individual’s perceptions, reactions, and conflicts, and also on the alliance and transference-countertransference that develops within the therapy. When two people are the operative system, attention is directed to the relationship itself—projections, communications, emotional regulation and attachment, and repetitive interactional cycles. Therapists who think in terms of a unit of three people look at coalitions, structures, and hierarchies of status and power. It is possible to do individual work in couples therapy, (looking at how the person’s past affects the present) and to do some couples work within an individual therapy model by examining the patient’s part in the cyclic transactions. The number of people in the room at a particular time may not be as important as how many people are involved in the therapist’s way of thinking about the problem. These concepts will be elaborated on below.

**Coupling and the life cycle**

**Marriage in its Historical Context**

Marriage is typically structured along two important factors: generation (parents are peers); and gender. America, in the mid-20th century, experimented with a highly gendered version of marriage. Interestingly and not often acknowledged, the function of marriage put forward by Parsons was not only to produce new citizens in the form of creating and raising children, but it was also to bind together in an intimate relationship two people in an effort to try to correct the defects of their personality development. Love-based marriage is a product of late Victorian Europe with a particular American twist of increasing egalitarianism. Increasingly, marriage has been seen as an institution by which people realize their most personal ambitions and fulfillment with their sexual relationship as the cornerstone of this fulfillment. Whether marriage can carry these heavy burdens remains to be seen, as the evolution of feminism and the increasing liberalization of women’s role in Western culture plays out. While women’s opportunity has continued to evolve through the institutions of law, religion, politics, commerce, and education, a corresponding and reciprocal modification of men’s privileges and responsibilities in the domestic sphere of child rearing has not evolved in a complementary fashion. Consequently, the last quarter of the 20th century has been marked by an ebb and flow of conflict and dissatisfaction, primarily on the part of women and manifested through the high divorce rate of roughly 50% (Whitehead 1997).

Westernized, current marriage practices are characterized by freedom to choose a spouse, equality in terms of marriage vows (though not necessarily in terms of marital roles), emancipation from relatives, and an increased emphasis on intimacy. Marriage, of all family relationships, is most distinguished by the peculiar set of power differentials dictated by gender. In an emotional sense, at the level of intimacy and connection, the couple are equal partners. The issue of power inequality in relationships bound by love is complex (Goldner et al. 1990), skewed by who has the greater earning power men’s greater physical strength, and the tendency of many women to marry men who are older and more successful than they are. In addition, the strong belief that women are in charge of children and the household makes it more difficult for women to have power in the world during the childbearing years (Gordon 2002). Women are more likely to diminish their investment in their careers or drop out of the labor force temporarily while their children are young, and during this time may experience a loss of earning power, career track mobility, and an internal sense of independence. It remains a great challenge for our society to establish a culture that truly recognizes and accommodates women’s growing independence and autonomy while allowing them the freedom to have time to raise their children. Couplehood consists of various forms throughout the life cycle as one can see below.

**Serial Relationships**

Between 1900 and 1960, the typical American life cycle included shorter courtships and long-term marriage with couples typically marrying in their early twenties. As people are living longer and divorce has become more acceptable, some individuals have sequential relationships that may include several marriages with the creation of two or three family units. It is often difficult to tell whether this model indicates emotional problems and fear of commitment, or whether it represents personal growth for the persons involved. A person who selects the same type of partner several times, or who goes directly from one partner to another without an effort to understand himself or herself or what happened to the earlier relationship, is more likely to perpetuate a dysfunctional pattern.
Cohabiting
In the US, living together as unmarried lovers has gone from being scandalous to normative in less than a generation. In other parts of the world, such consensual unions have been common for centuries. Couples cohabit for many reasons, ranging from convenience to a trial marriage to a permanently committed relationship for emotional or economic reasons that avoid a legal marriage contract. Cohabiting couples have both the advantages and the disadvantages of a looser relational contract, including a sense of freedom, aliveness, and uncertainty. Although the basic tasks of couple coalition, dealing with intimacy, power, boundaries, and sexuality are present, by definition cohabitation implies less agreement on beliefs about permanence, for example, what the couple’s status means, and also implies more permeable boundaries with the outside world than are found among married people.

Early research on cohabiters suggested that those who married after cohabiting were more likely to divorce (Messinger 1976). The reasons for the finding were never quite clear, although in the 1960s and 1970s one common explanation was that people who were unconventional enough to cohabit were more willing to behave in other unconventional ways, for example, by seeking divorce. In more recent cohorts in which cohabitation is more frequent, the differential in dissolution rates has been declining and has even reversed slightly (Schoen 1992). Approximately 40% of cohabiting couples live with children from one or both partners. Research (e.g., Isaacs and Leon 1988) suggests that living with a biological parent and the parent’s lover is an extremely difficult situation for children, who are asked to relate to a person who may leave them and has no real rights to discipline or parent them yet who cannot be ignored. Evidence suggests that both physical and sexual abuse is more likely with a biologically unrelated adult in the house. While children from former relationships are in the house, cohabitation should be limited to permanent or soon-to-be-married couples, whenever possible, to avoid children becoming attached to other adult figures that may leave them as their primary parent did. These multiple attachments and losses can be traumatic for children although many children handle these transitions without significant problems.

Marital Separation
Separation is a relatively common crisis of marital life. Although it is emotionally traumatic for the individuals involved, it can serve as an opportunity to reassess the marital contract and individual goals and sometimes can lead to a renewed and more functional marriage. Different precipitants may have brought about the separation; therefore, different issues may need to be addressed. For some couples, differences in adult development lead to a situation in which partners no longer have much in common. Spouses whose children are grown and have left home may not easily become accustomed to living alone together as a marital couple. With the parental role diminished or absent, there may be little emotional or functional viability left in the marriage.

Although it is natural to think of marital separation as an unfortunate event, it can also be viewed as symptomatic of the marital-system problems that need attention. In this sense, separation and its subsequent resolution may offer the potential for growth and change for the better. Trial separations can be useful to provide a cooling-off period for couples whose difficulties seem insurmountable. It offers the partners the opportunity to examine their relationship more objectively. At the same time the individuals can test their ability to adapt to living alone. This separation, together with new life experiences of various sorts (which may not have taken place had the couple stayed together), will often enable the husband and wife to change their behavior and feelings toward each other by the time they attempt reconciliation. Sometimes one of the spouses may use separation to manipulate the other spouse, or the separating person may move immediately into a new relationship. If the partners are unable to communicate with each other or learn about themselves, the separation will not be much help, regardless of whether the couple reconciles. Clinical experience suggests that about half of those couples that separate get back together; of those couples, about half divorce later on.

Divorce
The divorce rate in most developing countries has been rising, although since the mid-1980s it has shown signs of leveling off. If the relationship has been long enough for true attachment to take place (about 2 years is considered long enough), divorce is one of the most painful experiences in anyone’s life.

Divorce is a process, not an event, with its own developmental path. It usually represents one in a series of transitions that began with marital dissatisfaction and may or may not end with remarriage. A number of authors (Kessler 1975, Salts 1979) have delineated stages of the divorce process. In summary, these stages include the following:

1. A pre-divorce phase involving growing disillusionment and dissatisfaction with the marriage and arrival at some consideration of divorce.
2. The separation itself, including moving out of the house and dealing with immediate grief. For many people, this is a period of great emotional distress, confusion, and grief—the so-called crazy time.
3. A period of 1–2 years during which the couple deals with reorganizing their life structure, parenting issues within the new family structure, financial and family reorganization, community status, and legal ramifications of divorce. Negative life stresses are most marked during the first 2 years following divorce. Children are most likely to experience diminished parenting during the period because of the parents’ preoccupation with divorce-generated problems. Children are likely to respond with noncompliant, angry, demanding, or depressed behavior.
4. For each spouse, reforming of an identity from being a part of a couple to being a single person occurs next. This phase occurs during the latter part of the process and concerns regarding children tend to decrease unless partners continue to use children as weapons in the divorce proceedings. The legal aspects of the divorce itself may take from 3 months in some states with an uncontested divorce to several years, depending on the laws and the amount of anger. The psychological
responses, but the degree of coregulation is much higher in social animals, the presence of familiar, supportive friends, and in good relationships decrease stress responses and between wishes for high levels of lust and for security.

troubling; the high frequency of affairs indicates the confl ict cannot be located or is not available during periods of consciousness often keeps new lovers from noticing, or taking seriously, the potential flaws in the relationship. Falling in love involves a complicated mix of cognition, feeling and behavior, as well as poorly understood biological connectors such as pheromones. Lust, which is a wish to connect with another person sexually, is more driven by testosterone and a different set of processes in the brain. The desire for sexuality may occur within a loving relationship, but sexual desire does not have to be “person focused,” as the frequency of “one night stands” indicates. Sexuality and attachment are usually interconnected; having a sexual experience frequently stimulates a desire for more closeness, and “falling in love,” with its increased dopamine, can stimulate the production of testosterone, so that once in a state of romantic love there is usually a desire for sexuality. As the relationship progresses (assuming it does) these processes subside and the couple moves into the more “companionate” phase of love, in which oxytocin most likely plays a crucial role (Insel 1997). This generally happens somewhere between 6 months and 2 years. At this point, there is a true attachment bond, with comfort, rather than euphoria, in closeness, and anxiety if the partner cannot be located or is not available during periods of stress. Generally during this phase, the intense sexual focus of the earlier relationship decreases, although sex itself can become more meaningful and emotionally connected. Some people find the loss of intensity, particularly sexual intensity, troubling; the high frequency of affairs indicates the confl ict between wishes for high levels of lust and for security.

Bonded partners regulate each other’s physiology, and in good relationships decrease stress responses and increase immune response. (Because humans are highly social animals, the presence of familiar, supportive friends, and in some cases, pets, can also affect stress and immune responses, but the degree of coregulation is much higher in romantically bonded couples. This occurs regardless of whether the couples are the same or opposite sex.) In highly confl icted relationships these protective mechanisms do not occur and there is a higher incidence of both physical and psychiatric disorders. (Graham et al. 2006). With the death or desertion of one partner, the incidence of anxiety, depression and serious illness or death in the other increases dramatically (Duffy 2005, Prigerson 1997).

Couples Development
Dym (1993) has described how couples relationships evolve over time. Members of couples are infl  uenced by past and present relationships and tend to form ties that have a distinct character that emerges through regular cycles of confl ict and resolution. Dym draws attention to broad, normative changes in couples, characterizing these developmental shifts as periods of expansion, contraction, and resolution. For example, in the early expansiv e years of a committed romantic relationship, the lives of two are in a sense woven into one. Some refer to this period of optimism, promise, and fusion as moving from “I” to “We.”

In the next years of the relationship, Dym describes a predictable stage of contraction and a feeling of betrayal, in which members of the couple reconnect with a need for an “I.” This desire can be marked by experiences of doubts, fears, and insecurities, and many couples retreat from their established routines. Partners may find themselves feeling “out of synch” with their own personal ambitions, describe themselves as feeling trapped or lonely, and may believe they are progressing at different tempos from each other. Stormy times may ensue with bitter confl ict and blame. During the resolution stage couples may resort to compromise, negotiation, or even a more radical restructuring of their relationship in an eff  ort to make room for both the individual and the relationship. In considering this dialectical movement from expansion to contraction to resolution, this cycle repeats several times over the course of the relationship. Dym notes that many couples have what he calls a “home base” where they tend to reside, in terms of the sense of “We,” “I,” or “working on it.” A home base is the point of the cycle of expansion and contraction where the couples find themselves most often.

The couple’s development is also strongly affected by the age of their children, if they have children, as the demands on the couple change dramatically as their children progress through different developmental stages. Couple development is also affected by the spouses’ place in the individual life cycle. For example, a man who marries at 26 may be far more work focused than family focused, while the same man at 50, in the same or a different marriage, may be far more willing to put time and energy into his intimate and family life if he has achieved suff icient personal and financial success already in the workplace. Periods of major questioning, developmental change, or stalled transition during the individual life cycle (especially at decade markers and the beginning of midlife) may destabilize marriages.

The Family of Origin and Couple’s Dynamics
The family of origin is not only of historical interest, but also serves as the crucible of the beliefs and behavior patterns that the partners bring with them into couplehood. In most couples, multiple family members, including parents,
stepparent, and sibs, are deeply involved in the couples' present life, especially during the early years of marriage and child rearing. The family's approval and acceptance of a partner, or conversely their disapproval or excessive intrusion, can have a major impact on the couple's life.

One of the first tasks of a new couple is to create a couple boundary while still connecting with the larger family (Carter and McGoldrick 1999). If the families approve of and support the new couple while allowing for appropriate boundaries, the couple develops a sense of being part of a loving system of people toward whom they can turn to for help if needed. However, if either partner privileges their sibs or parents over the new spouse consistently, the sense of safety and security of the marriage is seriously compromised. If a parent disapproves of the new family member and their adult child sides with the parent, problems are inevitable. If the adult child acts helpless or declares themselves "caught in the middle" and unable to privilege the new relationship, the partner will not be able to develop a sense of trust. Sometimes the new spouse will take up arms in the secret battle that their partner has had with a parent, thus becoming the "bad guy" while the adult child looks like the "good guy" (resulting in conversations such as "oh, we can't come to visit because my wife doesn't want to"). To preserve the couple, the child of the disapproving parent must be willing to deal with their parents directly, by at least, refusing to listen to critiques of their spouse either in public or in private, by insisting on civility during family gatherings, and by making it clear that "new couple house rules" (for example, no candy for the children) be followed.

Frequently couples develop a "family of heritage"—that is, they tend to lean more toward the traditions, rituals, and holidays, of one of the families more than the other. Often the family of the wife becomes the family of heritage, since in this culture it is more usual for a woman to remain close to her mother than for a son to remain close to his (and since women still tend to do a larger share of the work of the family ritual building). If one family lives nearer than the other, or if one family is noticeably more psychologically functional or more powerful in the community, these factors will also affect family ties. Partners in marriages which cross religious, cultural, or class boundaries have to work harder and more deliberately to develop their own traditions and find ways to include both families.

Contact between different generations varies over the life cycle, tending to increase when help is needed, particularly with the presence of young children or illness in either generation, and to decrease if the children of the younger couple are grown and the grandparents are still vital (Combrinck Graham 1985). Family businesses, which force family members into constant touch, have their own strengths and difficulties (Gersick et al. 1997).

The Culture and the Couple's Dynamics

No couple functions in a vacuum; they are constantly impacted by the larger system issues of race, class, ethnicity and gender which to some extent define possibilities and constraints for couplehood. It is important to consider both the larger American cultural norms, and those of the multiple subcultures in which the couple might be embedded. For example, nonmonogamous marital relationships may be generally thought unacceptable for either partner in the wider American culture, acceptable for many only in some subcultures, and acceptable for both partners in gay male culture. The lack of job opportunities and increased risks of physical danger for African American males may make marriage and gender roles different, and in some ways more difficult, for African American couples than for European-American privileged couples. Living in an Orthodox Jewish community in which large families are common, an Orthodox couple may have multiple children, while the same partners, living in a less religious framework, might have felt the need to have only one or two. Gender, race, and class are inextricably mixed in the development of power and marital roles that affect how the couple structures their lives. Couples in therapy should be specifically asked about the norms of their immediate social systems and subculture (and whether they follow or disregard them). Unless the therapist lives in the same social system, one cannot assume that they understand the norms of the couple's community.

Secrets and Confidentiality in the Relationship

Unless a therapist sees both parties together at all times, he/she will eventually face a situation in which family secrets are disclosed in individual sessions. Since secrets are a common source of dysfunction, discovering and dealing with them is a frequent occurrence. As Imber-Black (1993) says, “secrets, decisions about secrecy and openness, and the management of information are woven into the fabric of our society. The paradoxes of what is to be kept secret and what is to be shared and with whom are all around us and are embedded in each encounter between family and therapist.”

The therapist needs to make a distinction between secrecy and privacy. Privacy is usually considered to mean information held by one person that they would prefer not to share but that does not directly affect their relationship with others. It usually implies a zone of comfort free from intrusion. Secrets are usually considered to be feelings or information that would directly affect a relationship. They are most often connected to fear, anxiety, and shame, and are often shared—that is, some people in the system know, whereas some do not. There is also a gray area in which different people have different ideas about whether the information is important or not. (Does a spouse consider an extramarital affair that ended 10 years ago private or secret?)

Secrets define hierarchy and relationships, leaving the unaware mystified and out of alliance. Some are about the past such as an affair many years ago, and some about the present such as an ongoing affair, or an impending bankruptcy. The majority of toxic secrets are in some way related to sex (including abortions and illegitimate birth), money, or betrayal.

In general, the best rule of thumb is that a secret should be disclosed if it is seriously affecting connections between people, posing danger to a family member (sexual abuse), or shaping family coalitions and alliances. In general, keeping secrets is such a serious barrier that it is better to disclose them, even if painful—because otherwise the sense of mystification and isolation in the unaware is
very strong. (This seems to be true in many areas affecting children that were formerly always kept secret, such as adoption, out-of-wedlock birth, and artificial insemination.) Such issues are, however, very dependent on situation. For example, if a husband is bisexual or homosexual and does not tell his wife but engages in unprotected (or even protected) intercourse with men, the wife is in serious danger and needs to know. Since the husband’s sexuality is definitely the wife’s concern, not telling her this secret is a serious threat to the relationship. However, some secrets (such as an affair of several years before) when disclosed to an insecure partner, may lead to such permanent anxiety that intimacy is compromised rather than increased. The therapist should be careful to leave this type of decision to the spouse, without urging one choice or another, but carefully reviewing the plusses and minuses of each approach.

The therapist must carefully consider the timing and type of disclosure. Premature disclosure, before the therapist has an alliance with the family or couple, can cause those involved to leave therapy with no place to deal with potentially explosive material. This is particularly true when there has been a history of violence or abuse. It is generally believed that if a patient refuses to disclose a secret so serious that therapy will be derailed, the therapist may terminate therapy but should not disclose the secret himself or herself. An exception is in cases of potential violence to another, especially in child abuse or threats to murder, where the therapist is required to report to the authorities and the potential victim, so the secret will have to be disclosed. The conflict many therapists feel—faced with the requirement for reporting and knowing this may end their relationship with the couple—is difficult to manage, and these cases must be discussed with a supervisor or mentor. Issues around disclosure also arise in cases where one partner is HIV positive and has not disclosed. Legally, the therapist is not obliged to do so—ethically, it is extraordinarily hard not to. The patient should be strongly urged to share this important information.

In the following section, guidelines for assessing and treating couples are offered. Although these guidelines do not sufficiently cover all couples’ problems and situations, they do represent a generic set of ideas that therapists may apply to the specifics of many marital issues.

**Evaluation of the Couple**

The evaluation of a couple involves obtaining data on the current point in the marital and/or family life cycle, why the couple approaches for assistance at a particular time, and each partner’s view of the marital or relationship problem (Table 93–1). Often the couple’s therapist will hold one individual session with each partner after the first or second conjoint session. This gives each partner an opportunity to divulge information that might otherwise not be obtainable. Issues of confidentiality need to be carefully addressed.

In formulating the marital difficulties, the evaluator will want to consider the couple’s communication, problem solving, roles, affective expression and involvement, and behavioral expression, especially in sexual and aggressive areas. The clinician will also want to evaluate gender roles, cultural and racial issues, and power inequities resulting from gender, class, age, or financial status. It is critical to ask about alcohol and substance abuse, health and reproduction, Attention Deficit Disorder, and violence (Table 93–2).

Even if the partners do not mention their children as a problem, it is wise to spend some time developing a sense of how the children are doing, whether or not there is a favored child or a difficult child, and whether the children are being pulled into marital conflicts. At times children can be the source of a couple’s conflict and at other times they may function as the glue that keeps the relationship together. If a large part of the couple’s difficulty centers around concerns regarding their children, family therapy may be the preferred treatment modality (see Chapter “Family Therapy”).

The therapist must also assess current relationships with parents, siblings, and friendship circles. Work—family balance issues are also critical to assess; one spouse’s preoccupation with work, or alternatively joblessness, may be a primary issue in the marriage. The clinician must always ascertain whether there is a concomitant psychiatric condition, especially on Axis I Disorders (see subsection “Treatment of Axis I Disorders”). If one exists, the impact of the condition on each member of the couple must be explored. In addition to major mental illness, substance abuse, paraphilias, and ADD are particularly likely to alter marital dynamics.

Other areas deserving special attention include each spouse’s commitment to the marital union and the couple’s sexual life. Assessment is complicated when one spouse is keeping commitment doubts or extramarital sex a secret. Conjoint and individual sessions with each partner may be needed. When infidelity or serious commitment questions arise, the therapist and couple must address whether or not the couple should stay together.

**Genograms for Evaluation**

A helpful device when evaluating a couple is the use of a genogram. The therapist can collect and organize historical
Table 93–2 Guidelines for Interviewing Couples—The Process

<table>
<thead>
<tr>
<th>Question</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Can you tell me about yourself? As individuals? As a couple?</td>
</tr>
<tr>
<td>(Joining, forming an alliance with each member and the couple, creating a safe place)</td>
</tr>
<tr>
<td>• What brings you here? How do you understand the problem?</td>
</tr>
<tr>
<td>What feelings does it elicit for each of you? (Developing an interactional problem focus)</td>
</tr>
<tr>
<td>• How does the problematic pattern actually work? Can you show me how it works? (Observing by staging an “enactment”)</td>
</tr>
<tr>
<td>• How did this pattern originate? How did you create it? (Placing the problem in context of their relationship, family of origin, and their own individual development)</td>
</tr>
<tr>
<td>• How have you maintained this pattern? What have you done to keep it going? (Placing the pattern or problem under their joint control)</td>
</tr>
<tr>
<td>• Tell me about what you believe should be happening. (Myths, stories, ideas, expectations about love, sexuality, marriage, and closeness)</td>
</tr>
<tr>
<td>• In what other ways is the pattern currently reinforced? What do your family and friends believe is the problem? (How do jobs, extended family members, and friends contribute to the pattern’s resilience?)</td>
</tr>
<tr>
<td>• Is this pattern always occurring or are there exceptions? (How pervasive is it, is it chronic, or related to a life transition?)</td>
</tr>
<tr>
<td>• What have you done to try to change the pattern? (Trying to avoid redundancy by inquiring about solution behavior)</td>
</tr>
<tr>
<td>• Have your efforts to change the pattern made things better or worse? (Looking at the problem as “attempted solutions”)</td>
</tr>
<tr>
<td>• What has been the influence of this problem in your lives? (Again looking for the “influence” of the problem over their lives)</td>
</tr>
<tr>
<td>• How motivated are you to change the pattern now? (Assessing individual and couples motivation)</td>
</tr>
<tr>
<td>• What would happen if you succeeded in changing the pattern? (Anticipating possible consequences of change, both positive and negative)</td>
</tr>
<tr>
<td>• What patterns of relating have you created that you want to keep? (Identifying and honoring assets and resources)</td>
</tr>
<tr>
<td>• Are you ready to make a change? How about trying something different? (Preparing the couple for exploring new patterns of interaction)</td>
</tr>
</tbody>
</table>

The therapist is then free to track themes (always keeping an interactional focus), invent tasks and experiments designed to provide new experiences for the couple, and to evaluate the changes that occur or do not occur as a result of the couple’s efforts to change their patterns of interaction.

Table 93–1 Example of a genogram.

Assessment of Concomitant Psychiatric Illness

Having a spouse with a serious Axis I disorder, such as anxiety disorder, mood disorder, or substance abuse puts realistic strain on the marital relationship. The marital interaction prior to, during, and following the onset of the symptoms in the spouse is influenced by numerous factors and is quite variant across dyads. It is incorrect to assume that in all cases the interaction between the spouses brought on, or caused, or even helped trigger the mental disorder and symptoms in the other. Indeed, a supportive spouse can allow a quite dysfuntional partner to continue to manage reasonably well. Whatever the symptoms in one spouse, the relationship of symptoms to the marital interaction is on a continuum and can take any one of the following forms:

1. The marital interaction neither causes the symptoms nor stresses the psychologically vulnerable spouse. The spouse may be a source of support, balance, and growth.

2. The marital interaction does not stress the vulnerable individual but following onset of symptoms the marital interaction declines and becomes dysfunctional, thus causing more distress.

3. The marital interaction acts as a stressor that contributes to the onset of symptoms in a vulnerable spouse.
4. The symptoms can be explained totally as under the control and function of the interactional patterns between the spouses.

The therapist meeting a new couple therefore can entertain a range of different ideas that may help illuminate and explain their distressing circumstances. The Axis I condition can be a useful focus and often is what brings the couple in for help.

**Indications and Contraindications for Couples Therapy**

The process of choosing a type of therapy is complex and research is just beginning to develop guidelines for such decisions. The therapist must most often base his or her judgment on clinical intuition, general clinical opinion, and the wishes and judgments of the people involved.

One of the most common questions for clinicians who are proficient in both individual and couples therapy, is to determine the timing and type of each therapy. The basic theoretical premise of couple/family therapy is that many problems are purely relational, that individual symptoms in one person can be viewed as interpersonal in terms of etiology or problem maintenance, and that they can be changed by altering the system. The basic principle of individual therapy is that problems or symptoms develop because of the biochemistry or dynamics of the individual, and that change occurs in the individual (either behaviorally or because of cognitive understanding of the problems) in the presence of an intense and exclusive relationship with the therapist. In truth, for many people, both forms of therapy may be useful or necessary. Self-knowledge does not always help the person understand the complex family system and how one’s behavior affects and is affected by family members. Family therapy often does not allow for intense exploration of psychodynamic issues. Individual therapy also does not allow the clinician to see how the problems of other family members may also be affecting the system. For example, a woman who requested individual treatment for depression was found on family evaluation to have a husband who had undiagnosed and untreated bipolar I disorder. Much of her depression was due to his behavior in manic or hypomanic states, and one of the key factors in treating her depression was treating his symptoms and having him acknowledge the truth of her concerns about him. On the other hand, for many people symptoms occur regardless of the different systems around them over time.

Since people tend to pick partners at similar stages of psychological development or maturity, it is not unusual for people with psychological difficulties to have spouses with similar or complementary degrees of psychological difficulties. In addition to the need to evaluate the partner, it must be recognized that such couples may create problem-maintaining systems that need to be addressed directly. Children in such families often suffer. The complex relationship between parent characteristics and child characteristics which determines which children are most at risk for developing symptoms, has been studied by, among others, Reiss et al. (2000) and Kendler (1996) either from genetically based similar illnesses (such as depression) or symptoms as a result of dealing with parental problems. These are often best treated with family therapy, but this does not rule out special time just for the child. For many people, both types of therapy are helpful, allowing for increased pleasure with the partner and also a context for personal and private growth.

The choice of timing of therapy is always of interest. If the person is highly symptomatic and has a problem which is usually amenable to medications, it is often helpful to begin medication and family psychoeducation/therapy first, in order to reduce the symptoms and educate the family, as well as to eliminate family sources of stress.

In general, one tries to deal with the most acute problems first. If it is possible in terms of timing and finances, it is easily possible to do individual and couples therapy at the same time. It is often recommended that the therapies be done by different therapists; however, in this strategy, it is imperative that the therapists remain in contact to avoid splitting or conflicting treatment. Some therapists have treated both the couple and one member of the couple individually, although this presents additional challenges to the therapist to remain neutral and unbiased. The therapist’s criteria depend more on the characteristics of the couple and how they function than on the particular diagnosis or problem area. The bias of the couple or individual must also be taken into account.

**Contraindications for Couples Therapy**

Couples therapy is not indicated for every couple in distress. In fact, at times, it may even be contraindicated. If one member is keeping an important secret, an attempt to work with them as a pair may fail and the therapist often has to take a strong stand and refuse to treat the couple, as in the case of an HIV positive male who refused to share this information with his wife. At times, one member of a couple may be too ill to benefit from couples therapy. This may be the case when one partner has a bipolar disorder or schizophrenia and is acutely psychotic.

Other couples feel more comfortable when each partner has his or her own therapist. At times it can be more effective to have each member in individual therapy with good coordination between the two therapists. Finally, cases may arise where seeing a couple together may put one member of the couple in physical danger. Some couples with a history of unilateral or mutual violence can work in couple’s therapy with a no-abuse contract. There is little data assessing the effectiveness of no-abuse contracts and the clinician would be naïve to assume that such a contract would protect their patient against future abuse. If there is a serious question about safety, the male (it is most often the man in these cases) may need to be referred to an appropriate anger management or abuse group.

Sex therapy may be contraindicated in the same situations as above. In addition, many couples do not feel comfortable in a therapy exclusively focusing on sex. These couples may make more progress if the sex therapy is carefully included in the overall treatment of the couple. When referring to a sex therapist, it is particularly important to be familiar with the skill and credentials of the therapist.

**Treatment**

We believe that for most people the strongest predictor of overall life satisfaction is the quality of the person’s central
relationship. In addition, it seems that a good and stable relationship buffers against the genetic vulnerability to both medical and psychiatric disorder. Thus, helping a couple achieve a more satisfying relationship can have widespread and profound influence on their life and lives of those with whom they interact.

The treatment of each couple is unique and may require a combination of couples therapy, individual therapy, group therapy (particularly self-help groups such as Alcoholics Anonymous) family therapy, and medication management. By using an integrative approach with each couple, the therapist maximizes the chances for success. Identifying goals of treatment will help determine which modalities will be most effective and in what order they need to be applied.

Goals most likely attained by employing couples therapy include the following:

- specification of the interactional problem
- recognition of mutual contributions to the problems
- clarification of marital boundaries
- clarification and specification of each spouse’s needs and desires in the relationship
- increased communication skills
- decreased coercion and blame increased differentiation and resolution of marital transference distortions.

Final goals of the marital intervention may involve the following:

- resolution of presenting problems
- reduction of symptoms
- increased intimacy
- increased role flexibility
- balance of power
- clear communication
- resolution of conflictual interaction
- improved relations with children and families of origin

The treatment of couples is often conceived of as a relatively brief therapy, 6–12 sessions, (though it need not be), usually meeting once weekly, with a focus on the marital interaction. The major indication for marital intervention is the presence of marital conflict but other indications include symptomatic behaviors that impact both parties such as depression, anxiety disorders, substance abuse, and illness in a child, marital partner, or other family member.

**Strategies and Techniques of Intervention**

Couples therapy utilizes strategies for imparting new information, opening up new and expanded individual and marital experiences, psychodynamic strategies for individual and interactional insight, communication and problem-solving strategies, and strategies for restructuring the repetitive interactions between the spouses or partners.

As the divisive spirit of the era of the earlier schools of psychotherapy recedes and pluralism and clinical pragmatism grows, clinicians attempt to integrate the various strategies into a coherent treatment approach that can be adapted to the individual case. The authors advocate an integrative marital therapy model that utilizes psychodynamic, behavioral, and structural—strategic strategies of intervention (see subsection “Treatment of Axis I Disorders”).

Evidence suggests that the diagnosis and symptom picture of one spouse and characteristics of the other spouse stand in complex relationship to the issues in the marital interaction and should, therefore, influence the planning of intervention, that is, the goals. For example, if one spouse has a nonendogenous unipolar depression with no clear precipitating stressful life events, the marital interaction could be a chronic stressor and contributor to the condition. Marital therapy in this situation could well be a preferred mode of intervention. On the other hand, if the spouse is suffering from a bipolar illness, manic episode, and the marital interaction has been good prior to the episode, psychoeducational intervention with the couple may be in order with little or no attention to the ongoing marital interaction.

Sometimes, couples present with chronic histories of unresolved and unrelenting conflict. Other couples are in a state of transition, perhaps moving from the initial expansion stage of their marriage to the inevitable crisis related to the reevaluation of the contraction stage. In either case, clarifying the couples’ process and their reoccurring patterns of behavior represents the starting place for couples therapy.

The focus should be primarily on the interpersonal distortions between husband and wife, and not on the couple–therapist transference. However, negative transference distortions toward the therapist must be addressed quickly and overtly.

There are three strategies in this focused, active treatment of marital discord:

1. The therapist interrupts collusive processes between the spouses. The interaction may involve either spouse failing to perceive positive or negative aspects of the other that are clear to an outsider (e.g., cruelty or alternately generosity) or when either spouse behaves in a way aimed at protecting the other from experiences that are inconsistent with the spouse’s self-perception, (e.g., husband working part time views himself as breadwinner, whereas wife works full time and manages checkbook to shield husband from reality of their income and finances).
2. The therapist links individual experience, including past experience and inner thoughts, to the marital relationships.
3. The therapist creates and allocates tasks that are constructed to (a) encourage the spouses to differentiate between the impact of the other’s behavior versus (the other’s) intent, (b) to bring into awareness the concrete behavior of the partner that contradicts (anachronistic) past perceptions of that partner, and (c) to encourage each spouse to acknowledge his/her own behavior changes that are incompatible with the maladaptive ways each sees himself/herself and is seen by the marital partner. These tasks also help reconstruct the couple’s narrative to make it more positive.

Among the above-mentioned tasks, (c) is most important. In fact, in the initial stage of marital treatment the authors ask that each partner focus on what they want to change in themselves, not how they want the other spouse to be different.
In this integrative model, the focus is on three related domains:

- the functional relationships between the antecedents and consequences of discrete interactional sequences
- the recurrent patterns of interaction including their implicit rules
- each spouse’s individual schemata for intimate relationships

In the initial stage, alliances must be developed between the therapist and each marital partner, with the therapist offering empathy, warmth, and understanding. The therapist must also ally with the couple as a whole and learn their shared language as well as their different problem-solving styles and attitudes.

Behavioral techniques, including giving between-session homework, in-session tasks, communication skills, and problem-solving training, can facilitate the process of helping marital partners reintegrate denied aspects of themselves and of each other. However, the focus is not on behavioral change alone, as overt behavior is seen as reflecting the interlocking feelings and perceptions of each spouse. Ideally, the process of treatment should be one where each partner can consider what they want to change in themselves as opposed to how they want the other spouse to be different; safely explores new beliefs, feelings, and behaviors; and experiments with new patterns of interaction that are unfamiliar and even anxiety-provoking.

**Treatment of Axis I Disorders**

With increasing evidence of the multiple causes (including genetic, neurochemical, familial, and environmental) of many psychiatric syndromes, attention must be paid to both individual diagnoses and family interactions. In the last 20 years as diagnostic categories have become clearer, our treatment approaches have also become clearer. Many DSM IV-TR diagnoses are now treated with pharmacotherapy at some point in the course of the illness. For example, antipsychotic medications are used to treat the positive and negative symptoms of schizophrenia while antidepressants are usually indicated when an individual is diagnosed with a major depression. In most instances, treatment is also indicated for the problems of a couple and interactions accompanying these conditions. Couples therapy has been shown to be effective in providing psychoeducation and enhancing compliance with medication and psychosocial interventions when one member is suffering from any DSM IV-TR diagnosed conditions including, but not limited to, schizophrenia (American Psychiatric Association Work Group on Schizophrenia 2004), depression (American Psychiatric Association Work Group on Depression 2000), bipolar disorder (American Psychiatric Association Work Group on Bipolar Disorder 2002), anxiety disorders, dementia, substance abuse, adult ADD and some Axis II conditions. Attention to and evaluation of the couple and family systems is specifically mentioned as part of the treatment plan in many of the recent practice guidelines of the APA. Disorders diagnosed in infancy, childhood, and adolescence such as pervasive developmental disorders, attention deficit disorder, conduct disorders, mood and anxiety disorders, and eating disorders most often require family therapy as part of the overall treatment program. We look forward to more data emerging to support the use of combination therapies which in our combined clinical experience has been the most effective way of aiding our patients suffering from major mental disorders.

Some of the problems may be related to the etiology of the individual illness, some may be secondary to it, others may adversely affect the course of the illness, and still others may not be connected at all. For example, if panic disorder with agoraphobia has developed in a spouse early in the marriage, the therapist’s attention must be directed not only to treating the illness but also to the nature of the marital interaction, including its possible role in exacerbating or ameliorating the illness. In addition, if a major psychiatric diagnosis occurs in one spouse, attention must be paid to the partner’s ability to cope with the illness. In fact, a recent study found that for some mother’s with borderline personality disorder, being a parent can lead to positive self-esteem, while other’s can be paralyzed by the difficulties of child rearing (Gunderson et al. 2006). A child may respond to his or her mother’s severe depressive illness by becoming a caretaker for a younger sibling, risking his or her own development, or the child may begin acting out. Moreover, the treatment of a child with a DSM IV-TR diagnosis will be greatly assisted by the couple’s recognition of the problem and adherence to the treatment program.

By way of example, let us look at the review of Prince and Jacobson (1995) which suggests that medication plus marital therapy is better than individual therapy alone. In these cases, individual therapy does little to moderate the “toxic” marital problems that increase the depression. Drugs alone are also ineffective for this type of problem. Most therapy for depression has been done on depressed women so we have little information on working with depressed married men. However, some men are deeply troubled by the experience of talking about problems, preferring to work on them in private. Many depressed men have wives who are very angry, which might increase their depression if discussed in therapy. Parenthetically, there is some evidence that women with other Axis I conditions such as substance abuse respond better to couples therapy than men with other Axis I conditions (Haas et al. 1990).

**Effectiveness and Efficacy of Couples Therapy**

There are two major sources for reviews of efficacy of couples therapy. Shadish et al. (1995) summarized 163 randomized studies, 62 marital, and 101 family therapy. Pinsof and Wynne (1995) in a commentary have summarized the data. These studies point to the following general conclusions:

1. Family treatment is more effective than no treatment. This conclusion is manifest in studies that contrast family and marital treatment to no-treatment control groups. Roughly 67% of marital cases and 70% of family cases improve. The outcome may be slightly better if the identified patient is a child or an adolescent than if he or she is an adult. These findings were statistically significant. No one therapy method was demonstrated clearly to be better than another.
2. The deterioration rate (i.e., the percentage of patients who become worse or experience negative effects of therapy) is estimated at about 10%—lower than for individual therapy. Pinsof and Wynne (1995) believe the rate is lower than 5−10% and describe family therapy as not harmful.

3. In several areas evidence indicates that family treatment is the preferred intervention strategy. In other areas family therapy and individual therapy were tied—often in situations in which the identified patient had a significant Axis I problem (Shadish et al. 1995). These treatments of choice are of great importance for practitioners and students.

Importantly, a recent study of effectiveness of treatment with long-term follow-up reported that, "of 300 couples enrolled, just under half completed the end-of-treatment assessment and just over 40%, a 2 year follow-up. Outcomes of treatment showed significant improvements in relationship matters, individual mental health, and enhanced coping abilities. At long-term follow-up, all results remained the same and some aspects improved for both sexes." (Lundblad and Hansson 2006). Although it is difficult to draw definitive conclusions from these studies, it seems that the preponderance of data suggests the effectiveness of couples therapy.

**Couple Distress or Problems**

The data over three decades suggest that couples therapy is superior to individual therapy for marital conflict situations (Pinsof and Wynne 1995). The strongest effects are for increasing marital satisfaction and reducing conflict. (It should be pointed out that these are not synonymous—some people who have high marital conflict still report high marital satisfaction, and some couples have low conflict because the marriages are “dead.”) Not surprisingly, couples who are less distressed show more improvement. Some of these effects wash out over time, as is common in chronic conditions.

What happens if the outcome of marital treatment is separation or divorce? One might automatically assume that such an outcome is deleterious and that marital and family therapy should be designed to hold the families together. On reflection, experience seems to indicate otherwise. Marital therapy allows the partners to examine whether or not it is to their advantage to stay together, and it gives them permission to separate if that is what they need to do. Clinical Vignette 1 illustrates a couple that had difficulties from early on in their marriage. In the course of treatment the couple decided to separate. It is important that the outcome of treatment be determined by the couple’s desires not by the therapist’s bias about whether a couple should remain together or separate.

**Clinical Vignette 1**

The couple presented for treatment in their thirties. He was a dentist, and she was a housewife who had previously been a teacher. She came from a family in which her father had been a chronic “run-around,” and she married her husband because he appeared to be reliable and stable. He came from a family in which the mother was dull and masochistic, and he married his wife because she seemed exciting and interesting.

The couple came to therapy after five years of marriage when it was “discovered that the husband was having extramarital affairs.” (He had left several notes from girl friends around.) Exploration of the situation revealed that soon after marriage Mrs. A. had become slowly and imperceptibly disillusioned with her husband when she found that he was very insecure about himself, was very unreliable, and characteristically “lied and cheated.” Dr. A. perceived after several years that his wife was not as exciting as he had thought and would not fulfill the role he had envisioned for her—that is, being the “slave” to a professional husband.

The therapy allowed the couple to examine some of the original premises on which they had gotten together and they found them faulty. The process of therapy, and not the therapist’s values, gave them the necessary permission to separate.

**Special Considerations for Couples Therapy**

**Ethical Issues in Couples Therapy**

The fundamental ethical dilemmas inherent in psychotherapy: confidentiality, limits of control, duty to warn/reporting of abuse, and therapist–patient boundaries become more complex when the treatment involves more than one person. The couple’s therapist has an ethical responsibility to everyone in the family. In some cases, individual needs and system needs may be in conflict. For example, a husband may wish to conceal a brief episode of unprotected sex with another woman, while his wife is better protected, for health reasons as well as psychological reasons, if she knows about it. A wife’s wish to be divorced from a psychiatrically ill and demanding husband may conflict with his need for her care. Such clinical situations provide a set of ethical dilemmas for the therapist. The therapist must be clear that his/her job in most cases (such as impending divorce) is to help the partners sort out their values, obligations, and options rather than making a decision for them. In some cases, however (such as the reporting of child abuse), reporting abuse is not just an ethical issue but also becomes a legal one. And in
some cases the therapist faces difficult gray areas which must be decided on a case-by-case basis. The therapist also has certain unalterable ethical obligations such as not engaging in “dual relationships” (see later) with patients or exploiting them for their own benefit.

While the operative concept is “first do no harm,” the issues of how one defines harm, and who will or will not be harmed by a certain action, are complex and difficult questions, especially when treating a couple or family.

The Conflicting Interests of Family Members
It is not unusual for the interests of each member of the couple to conflict at some point. Borzormenyi-Nagy and Spark (1973) years ago emphasized the contractual obligations and accountability between persons in the multigenerations of a family. Relational ethics are concerned with the balance of equitable fairness between people. To gauge the balance of fairness in the here-and-now, and across time and generations, each member must consider both his/her own interests and the interests of each of their partner. The basic issue is one of equitability, that is, everyone is entitled to have his or her welfare and interests considered in a way that is fair to the related interests of other family members.

There may be times when it is difficult to decide whether a therapeutic action or suggestion may be helpful for one individual, but not helpful or even temporarily harmful to the other individual. In their concern for the healthy functioning of the system as a whole, therapists may inadvertently ignore what is best for one individual. An ethical issue is how the decision is made. Should it be the therapist’s concern alone or should it be shared with the couple? How much information should they be given on the pros and cons of modalities? The authors’ bias is to negotiate and give the couple all the relevant information so that they can make the most informed decision possible (for further discussion, see also Hare-Mustin et al. 1979, Hare-Mustin 1980).

Boundaries
The issue of boundaries and dual relationships is a critical one in all forms of psychotherapy. Because couples therapy involves more than one patient in the consulting room, there is less likelihood of inappropriate sexual contact between therapist and patient. However, there have been cases in which a therapist, working with a couple, began an affair with one of the spouses, either during couple’s therapy or after the couple separated. The American Psychiatric Association (APA) and The American Association of Marital and Family Therapy (AAMFT) (1998) have a very sensible code of ethics making clear the inappropriateness of this kind of behavior. The American Psychological Association’s position is consistent with these other organizations.

Oftentimes the therapist may find that the couple faces the same issues that the therapists face in his or her own life. It is vitally important for the therapist to recognize his or her countertransference reactions to avoid taking sides in the therapy session. For example, seeing a couple going through a separation at the same time one is going through the early stages of one’s own divorce is an extremely difficult thing to do, and it may be very difficult to remain neutral during therapy sessions. While it is obviously impossible for a therapist to stop treating patients while going through a divorce, he or she could certainly choose not to accept a new patient whose situation is very similar to their own or who reminds them of their departing spouse.

“Confidentiality” and “boundaries” issues are mentioned in the Code of Ethics of AAMFT (1998) Three of these have special relevance to couples therapists:

1. Marriage and family therapists are aware of their influential position with respect to patients, and they avoid exploiting the trust and dependency of such persons. Therapists, therefore, make every effort to avoid dual relationships with patients that could impair professional judgment or increase the risk of exploitation. When a dual relationship cannot be avoided, therapists take appropriate professional precautions to ensure judgment is not impaired and no exploitation occurs. Examples of such dual relationships include, but are not limited to business or close personal relationships with patients. Sexual intimacy with patients is prohibited. Sexual intimacy with former patients for 2 years following the termination of therapy is prohibited.

2. Marriage and family therapists respect the right of patients to make decisions and help them understand the consequences of these decisions. Therapists clearly advise a patient that a decision on marital status is the responsibility of the patient.

3. Marriage and family therapists have unique confidentiality concerns because the patient in a therapeutic relationship may be more than one person. Therapists must respect and guard confidences of each individual patient.

Financial Concerns
Who pays the bill is relatively simple in individual treatment with adult patients, but is not necessarily so in couples therapy. Determining who pays the bill can become especially tense in marital treatment of spouses in conflict. For example, if both spouses have insurance coverage from their respective employers, the question arises as to whose insurance should be used? This becomes most delicate when the spouses have conflicting views of the matter for any number of reasons, for example, “I don’t want my secretary seeing the insurance forms,” “using my insurance makes me the patient,” and so on. As with many concrete issues of conflict, the family therapist should approach the matter with a sense of fairness. The symbolic meanings of who pays should be thoroughly explored. When both partners have separate income and separate financial arrangements, they should each pay half the bill. Other financial questions involve sudden changes of fortune. If a woman married to a well-to-do man divorces her and her income drops severely and suddenly, should the therapist be willing to continue treatment even if the husband refuses to pay? For many therapists and many patients, money is the most taboo subject, even more than sex. It is the therapist’s job to clarify their own understanding and feelings about money so they can support discussions with patients.

Sexuality and the Treatment of Sexual Dysfunction
It is important to emphasize that there are substantial differences in frequency, type of preferred sexual activities,
and meanings implied by sexual behavior by gender, gender orientation, and in different cultures, different regions of the world. For example, premarital sexual activity is common in our current society buts remains unacceptable for women in many countries. Contrary to popular belief, there is no universal trend to earlier sexual intercourse, but the shift to latter marriage in most countries has led to an increase in pre-marital sex (higher in developed than in nondeveloped countries) and higher in men than women (Wells et al. 2006). Studies consistently show that married people have the more sex than single people (Laumann 1995). Twenty-five years of experience in treating sexual difficulties with some combination of sex and couples therapy has shown the combination to be consistently superior to individual therapy in the treatment of sexual dysfunction. Although the original success rates of Masters and Johnson (1970) have not been repeated in later studies, 60–95% of sexual dysfunctions can be treated, depending on the type of sexual problem. Recent advances in sex therapy have seen a movement from mostly behavioral to more integrative treatment models with more attention to cognitive and systemic factors, and increasing focus on organic causes and medical treatment for male dysfunction, especially erectile dysfunction (Rosen and Lieblum 1995).

Sexual Functioning of Couples

Schnarch (1997) contends that for many married people the magnetic force that drew them together eventually weakens to the point where sexuality and eroticism play a minor role in their lives. Sometimes, specific problems in sexual functioning affect the couple’s relationship. Although the DSM-IV-TR (American Psychiatric Association 2000) and most of the early sex therapists make a dichotomous distinction between sexual function and dysfunction, sexuality is probably best thought of as a set of experiences on a continuum of satisfaction. It is possible, for example, to have a sexual life in which there is, physiologically, sexual arousal and orgasm, but the experience feels passionless and boring, while the same “functioning” couple could have more passionate and exciting sex after therapy. It is possible to have an erotic sexual experience even if there is technical “dysfunction” as in the case of the male partner being unable to achieve erection because of physical illness, but the couple uses other methods of sexual expression. It is possible to have a satisfying sexual experience even if there are serious arguments between the couple around issues of frequency or type of sexual practice. There is an old wives tale that men use sexual intimacy in relationship in place of verbal intimacy. In our experience, this pattern may exist and be used by women as well.

It has been estimated that 50% of American marriages have some sexual problems. These can be divided into “difficulties” (such as inability to agree on frequency) which are clearly dyadic issues; and dysfunction which are specific problems with desire, arousal, and orgasm, as listed in the DSM-IV-TR (American Psychiatric Association 2000). Dysfunctions may be organic or psychological at base, and may be lifelong or acquired, generalized or situational. They may be deeply embedded in relational power or intimacy struggles, or may be the only problem in an otherwise well-functioning relationship. While most family therapists believe that there is no uninvolved partner when one member of a couple presents with sexual dysfunction, that is different from saying that the relationship itself is the cause of the dysfunction. The job of the therapist is to ascertain as best as possible the etiology of the problem and to choose the most effective therapy, whether medical, individual, or relational. It is also within the therapist’s purview to inquire about whether the couple would like to improve a technically functional but not very satisfying sexual relationship, in the same way that the therapist can offer methods or B to increase intimacy in a couple that wishes personal growth.

Diagnosis/Systems Issues

Sexual dysfunction or dissatisfaction is seldom caused by a psychiatric disorder (although depression and anxiety may often decrease sexual desire). It is commonly caused by ignorance of sexual anatomy and physiology, negative attitudes and self-defeating behavior, anger, power, or intimacy issues with the partners, or medical/physiological problems. Medication side effects are a particularly common cause of sexual dysfunction in patients who are receiving selective serotonin reuptake inhibitors (SSRIs). Male erection problems are proving increasingly amenable to medical forms of treatment such as prescription use of Sildenafil Citrate. It is also important to remember that people vary enormously in the importance they place on sex or eroticism in their lives. For example, in The Social Organization of Sexuality: Sexual Practices in the US (Laumann and Michael 1994), about one-third of the people surveyed have sex at least twice a week, about one-third a few times a month, and the rest, have sex with a partner a few times a year or not at all. In general, when sex is not part of a marriage over a long period of time, the relationship has less vitality and life. However, even well-functioning marriages may have periods in which sexuality is much less part of their lives (such as after the birth of a first child, or during a family or health crisis). Different people have vastly different tolerance for such periods.

Some Parameters of Sexual Function

Healthy sexual functioning can be thought of as resulting from relatively nonconflicted and self-confident attitudes about sex and the belief that the partner is pleased by one’s performance. In this type of situation, a reinforcing positive cycle can be activated.

However, when either partner has doubts about his or her sexual abilities or the ability to please the other, his or her sexual performance may suffer. This self-absorption and anxiety will characterize trically produce a decrease in sexual performance and enjoyment and can lead to impotency and orgasmic difficulties. Couple and individual difficulties of various sorts might then follow. A vicious cycle may be activated, with worries being increased, leading to increasingly poor sexual performance.

Because sex is a way of each person being vulnerable to the other, it is difficult to have sex when one is angry or not in a mood to be close (although some people can block out other feelings and keep the sexual area more separate). In addition, people who feel abused, mistreated, or ignored in a relationship are less likely to want to please the other. For some who feel that they have no voice in the relationship, lack of desire is sometimes the only way they feel able to manifest displeasure.
Assessment of Sexual Problems

Couples who continue in marital or individual treatment for long periods of time can resolve some of their marital problems, but can still suffer from specific sexual difficulties in their marriage. It is also true that specific sexual problems may be dramatically reversed after relatively brief periods of sex therapy, even though such problems may have proven intractable following long periods of more customary psychotherapy. However, sexual functioning which is suffering because the partners do not want to be close is not likely to respond to sex therapy unless other issues are also addressed.

Usually, when a marital couple has a generally satisfactory relationship, minor sexual problems may be only temporary. Resolution of sexual problems, however, will not inevitably produce positive effects in other facets of a relationship as well.

Marital and sexual problems interact in various ways:

1. The sexual dysfunction produces or contributes to secondary marital discord. Specific strategies focused on the sexual dysfunctions would usually be considered the treatment of choice in these situations, especially if the same sexual dysfunction occurred in the person’s other relationships.

2. The sexual dysfunction is secondary to marital discord.
   In such situations, general strategies of marital treatment might be considered the treatment of choice. If the marital relationship is not too severely disrupted, a trial of sex therapy might be attempted because a relatively rapid relief of symptoms could produce beneficial effects on the couple’s interest in pursuing other marital issues.

3. Marital discord cooccurs with sexual problems. This situation would probably not be amenable to sex therapy because of the partners’ hostility to each other. Marital therapy would usually be attempted first, with later attention given to sexual dysfunction.

4. Sexual dysfunction occurs without marital discord. This case might be found in instances where one partner’s medical illness has affected his or her sexual functioning, forcing the couple to learn new ways to manage the change. Another example might be when one partner has a history of sexual abuse or a sexual assault that creates anxiety related to the sexual experience. While individual therapy can be helpful in both of these cases, couples therapy can be especially useful in creating a safe place to address painful feelings and anxious expectations, and to provide education and guidance for couples undergoing these transitions.

Evaluation of Sexual Disorders

A careful evaluation of the couple’s total interactions needs to be done by the therapist as well as a physical assessment when dysfunction is present. When it appears that the basic marriage is a sound one, but that the couple suffers from specific sexual difficulties (which may also lead to various secondary marital consequences), the primary focus might be sex therapy per se. In many cases, however, specific sex therapy cannot be carried out until the relationship between the two partners has been improved in other respects; indeed, the sexual problems may clearly be an outgrowth of the marital difficulties. When marital problems are taken care of, the sexual problems may readily be resolved. It may be difficult to disentangle marital from sexual problems or to decide which came first. The priorities for therapy may not always be clear.

The DSM-IV-TR (American Psychiatric Association 2000) recognizes the following as dysfunctions:

- Sexual desire disorders: hypoactive sexual desire disorder (HSDD), sexual aversion disorder
- Sexual arousal disorders: female sexual arousal disorder, male erectile disorder
- Orgasmic disorders: female orgasmic disorder, male orgasmic disorder, premature ejaculation
- Sexual pain disorders: dyspareunia (not due to a general medical condition), vaginismus (not due to a general medical condition), vaginismus (due to a general medical condition).

Many people have more than one dysfunction (e.g., HSDD plus orgasmic disorder) and frequently each member of a couple will have a dysfunction, for example, premature ejaculation in the man with hypoactive desire in the woman. It is important to understand the sequencing of the onset of the dysfunctions to understand how they influence each other. As we have said, many sexual problems are not dysfunctions but are relationally based dissatisfaction.

Specific techniques are available which have been devised for eliciting a sexual history and for evaluating sexual functioning. The marital therapist should become familiar with these ideas and obtain experience in their utilization. A systemic assessment of sexual difficulties includes, at the minimum, the following details as listed in Table 93–3.

<table>
<thead>

</table>
In addition, in couples where there is any possibility that the problems may have an organic component, it is crucial to insist on a medical workup. This is particularly important for men, for whom small physiological changes in potency may produce anxiety that exacerbates the problem.

The taking of an intimate sexual history of husband and wife should, of course, be conducted with the couple without children present. The process of taking a sexual history should be handled with care and regard for each person's level of comfort.

What type of language should be used when discussing sexual topics? Obviously, one should not use terms that would be offensive or uncomfortable for either the therapist or the couple. At the same time, care must be taken to avoid using bland generalities which fail to elicit specific sexual information. Frankness is encouraged, and when there is vagueness, the therapist needs to follow up with more specific questions.

The therapist should use simple language or use the simplest technical sexual term that the patient is comfortable with. Some patients will misunderstand technical terms. For others, the use of the vernacular by the therapist may be inappropriate. The problem faced in the choice of language is itself an indication of our general cultural discomfort with sexuality. The therapist's own use of a particular sexual vocabulary can be a model to help the marital partners feel comfortable in communicating with each other more openly.

Taking a sexual history of lesbian and gay couples may be particularly difficult for a heterosexual therapist, either because of discomfort with homosexuality or lack of knowledge of homosexual norms and mores. In addition, the couple may have a wider or different set of sexual practices than the therapist is used to (of course, this may be true with heterosexual couples as well). Therapists have the options of educating themselves about homosexual sexuality, either by reading books available in mainstream bookstores about gay and lesbian life, and/or asking the couple about their own and other common practices. If the therapist is very anxious in this situation, he/she must decide when the therapy is not proving effective and if he/she should refer to another therapist. Gay and lesbian couples may present with any of the dysfunctions or dissatisfaction of heterosexual couples.

**Individual, Couple, or Sex Therapy for Sexual Problems**

This distinction was clearer 10 years ago when sex therapy was primarily focused on a specific and highly detailed behavioral protocol. Sex therapy in the last few years has moved in the direction of further understanding of the physiologic causes of sex dysfunction on one hand, and cognitive–behavioral issues on the other. It is clear at this point that, in general, sexual problems do not disappear with couple therapy unless specific attention is paid to the nature and quality of the sexual problems. Usually, it is most effective to deal with severe couple conflict before beginning to deal with sexual issues directly (Table 93–4). Sex therapy includes education, a focus on the intimacy and power aspects of sex, and often homework assignments that in some way deal with sexual anxiety and expansion of sexual options. Individual therapy is indicated if the problems are clearly related to the partner’s history (sexual abuse, hatred of women), have occurred in multiple relationships, and are not amenable to being worked on in the couple. Individual therapy is the most inefficient way of dealing with most couple-centered sexual problems. It is also important to consider the possible role of organic problems in any dysfunction.

<td>Strong attachment to marital partner; both partners interested in reversing the sexual dysfunction.</td>
<td>Couple not committed to each other; there are covert and/or overt behaviors to dissolve the marriage.</td>
</tr>
</tbody>
</table>

Recent research has demonstrated that no single school of therapy is definitively superior to another (Shadish et al. 1995). In general, the trend in the last few years has been toward a more integrative approach, drawing from a variety of models and allowing for a more fluid type of work (Lebow 1997). Integrative models are likely to combine some form of here and now work (cognitive or behavioral) with some type of historical understanding of the patterns that led to the current problem.

**Treatment of Sexual Dysfunction**

Treatment of psychosocial disorders, in the form developed by Masters and Johnson (1966), consisted of a thorough assessment of the partners and their relationship, education about sexual functioning, and a series of behavioral exercises. These sensate focus exercises were designed predominantly for behavioral desensitization, but also functioned to teach the partners about their own and the other’s sexual desires, and also served to elicit relationship problems. In these exercises, the couple pleasures each other, alternating in the role of giver and receiver, first in nongenital areas, then genitally, and then with intercourse. In the traditional form, intercourse is prohibited during the early stages to remove performance anxiety. There are also specific exercises for each of the sexual dysfunctions (Table 93–5). Different authors developed different exercises and ways of approaching

**Table 93–5 Marital and Sexual Problems Interact in Various Ways**

| Sexual dysfunction produces or contributes to secondary marital discord. Sex therapy is preferred. |
| Sexual dysfunction is secondary to marital discord. Marital therapy is preferred. |
| Marital discord cooccurs with sexual problems. Marital therapy first, with later attention given to sexual dysfunction. |
| Sexual dysfunction occurs without marital discord. Sex therapy is preferred. |
them. For a complete description of these exercises, we recommend Kaplan (1995), LoPiccolo and Stock (1996), and Zilbergeld (1992). This method works best when there is ignorance, shame, or specific dysfunction such as premature ejaculation. These exercises are difficult to complete if the couple feels angry or unloving toward each other.

Many of the patients who saw Masters and Johnson in the 1970s had sexual difficulties related to sexual ignorance and inexperience. Two decades later, the increase in premarital sex and the proliferation of easily available articles and books on sexuality and information on the Internet have decreased the number of these couples, and allowed some couples with sexual dysfunction to work on their problems at home. Recent studies of couples requesting sex therapy have shown a higher proportion having concomitant, complicated marital problems. Recent writers in the field, notably Schnarch (1997), have focused on cognitive/emotional issues in sexuality, and especially on the meanings attached to a particular act, and the level of intimacy involved. Having learned a great deal about the more mechanical and organic components related to arousal and orgasm, it is important to rethink other aspects of sex, such as eroticism, passion, mystery, and dominance/submission which make the act itself meaningful. This is particularly true in areas of sexual boredom or situational lack of desire. These therapists do not use rigidly staged exercises, but focus on the couple’s relatedness during sex; they may, however, suggest specific homework to help a couple focus on a particular aspect of their sexuality.

Although not mentioned in the DSM-IV-TR, sexual compulsions or addictions may be seen in couples. In these cases, one partner’s unceasing compulsion to think about, view (print or on-line), talk about, and/or have sex may be very wearing to the other partner or to oneself. A key component of this problem is that such persons may become extremely anxious if sex is denied. They may present with multiple affairs or with constant demands on the partners. However, most people who have affairs do not have a sexual compulsion.

Treatment for these disorders is still controversial. Some therapists use a 12-step addiction model along with group therapy; some treat it as a compulsion with individual therapy and medication (particularly with SSRIs such as fluoxetine). Couples therapy is still a critical component part of treatment—to educate the couple, and if multiple affairs have taken place, to discuss the viability of the marriage.

In recent years, emphasis has shifted to the role of biomedical and organic factors in the etiology of sexual dysfunction, along with the growing use of medical and surgical treatment interventions. Particular focus has been given to their role on vascular disorders and neuroendocrine problems, as well as the tendency for many medications to effect sexual functioning. It is critical for the patient to have a thorough physical workup. For a good review on the interaction of medication and sexuality, see Abramowicz (1992).

A variety of medical approaches to the treatment of erectile disorders in men have been developed in recent years. These include, but are not limited to, surgical prostheses or penile implants (seldom used in the last few years), intracorporal injection of vasoactive drugs such as papavarine, constriction rings and vacuum pump devices, and urethral suppositories. In 1998, oral medications for the treatment of impotence were introduced (sildenafil, Viagra). Because our understanding and treatment of impotence is developing so rapidly, it is important to stay current on new research in the field. Surgical treatments are available for the correction of arterial insufficiency or venous leakage problems. These methods may be more or less acceptable both to the man and his partner. The partner’s response to the changes is often a key element in their success. There has been some success in treating premature ejaculation with SSRIs and clomipramine; however, since these may also decrease sexual desire, caution and careful monitoring are indicated (Abramowicz 1992). Buproprion is sometimes helpful in preventing loss of sexual desire in patients treated with SSRIs.

In women, most medical interventions have been for dyspareunia. Female dyspareunia due to the decreased lubrication of aging can be treated with topical estrogen cream or lubricant jelly. Even when an organic cause is found and treated, the conditioned anxiety and lack of arousal associated with sex usually require an additional course of couples therapy with a sexual focus (Clinical Vignette 2). Hormone treatment for lack of desire has not proven effective (Rosen and Lieblum 1995).

---

**Clinical Vignette 2**

Mrs. L. had problems with anger during adolescence, generally due to feeling neglected by her busy parents. She had a period of intense sexual activity during adolescence, which was related to looking for affection through sexuality; she reported that she had no sexual problems during this time. Through twice a week individual psychotherapy in her twenties she worked through these problems, married Mr. L., and had a child. Mr. L. was a kind but rather distant man who soon after the marriage made a series of career moves that made him extremely busy. For the first two years, there were no sexual problems. Two years after the marriage, marital problems developed, and Mrs. L.’s desire decreased. Mr. L. then became more sexually demanding. Frequency and enjoyment of sex for both partners was markedly decreased. Mrs. L. refused to have sex, saying that she was too upset. When they had sex, occasionally however, both were orgasmic.

Mr. and Mrs. L. had both been raised in traditional backgrounds, and had been taught that sex should not be discussed. Although both had previous sexual experiences, they were unable to talk about their sexual problems. Mrs. L. also began fantasizing about other men. Although fantasies of other partners are not unusual, Mrs. L.’s fantasies only occurred when she was particularly angry with her husband. Whereas at one time individual psychotherapy for Mrs. L. might have been the treatment of choice, the therapist decided to use both marital therapy and sex therapy. Marital therapy helped to open communication between the couple. It was discovered that Mrs. L. was feeling very abandoned by her extremely hard working husband and feeling that she was being ignored—she had been in her childhood. In addition, she was angry at her husband for not helping with child-rearing responsibilities. Her fantasies about other men, which seemed to be a way of wishing for the original affection she craved, were upsetting her and making her wonder if she loved her husband. Mr. L.’s inability to challenge her...
and insist on her connecting with him emotionally before demanding sex was experienced as further withdrawal.

The couple was encouraged to deal more directly with their differences and with the disappointments underlying their anger. Issues related to each partner’s family of origin were brought up. Roles were restructured—Mr. L. took over more of the child-rearing responsibilities. As the marital relationship improved, their sexual problems decreased. The couples were also given a series of sensate focus exercises in which they were asked to focus on giving and receiving pleasure. They were encouraged to talk with each other about their sexual wishes and to pay attention to the connection between themselves while being sexual. They also discussed deepening their nonsexual physical connection, that is “constructing” a new reality for themselves as a couple.

This case demonstrates the use of combining different models and strategies to change behaviors which are complex in origin.

Homosexuality or Bisexuality

The authors believe that couples therapists should be adequately educated in the area of human sexual orientation and sexual identity. These terms in themselves are confusing. Sexual orientation is another way of indicating an individual’s tendency to be attracted to one or both sexes. Sexual orientation, like most psychological phenomena, is not an absolute or mutually exclusive trait. One may be sexually attracted to the opposite sex, the same sex, or both. Sexual orientation falls along a continuum, with completely homosexual and completely heterosexual preferences falling at the extreme ends, and many gradations in between. Sexual orientation may also change over time. Some persons change from heterosexual to homosexual or the reverse in their thirties, forties, or fifties. Some remain bisexual during their adult lives. Some persons may move along a continuum of homosexual to transgender. Sexual identity describes how a person identifies related to their sexual orientation. Hence a man who exclusively prefers women will usually have a straight or heterosexual sexual identity, and a woman who exclusively prefers women usually a lesbian or homosexual sexual identity.

Observations of human sexual behavior, affectional attachments, erotic fantasies, arousal, and erotic preference have suggested that sexual orientation and identity are not static. In fact, both may fluctuate over a person’s lifetime. Sometimes changes in sexuality are “just phases”; sometimes they become the predominant disposition of sexual relation. Regardless, deviation from heterosexuality in Western society is frequently accompanied by rejection, not only by one’s immediate family, but also by one’s peers and, in some cases, society in general. Accusations of discrimination and violence, “gay bashing,” have been a constant news story in metropolitan headlines. Bisexuals have the added nonacceptance by gay and lesbian friends or associates who may accuse them of “fence-sitting,” of “sleeping with the enemy,” or of being deviant because they are unable to choose whether to be heterosexual or homosexual. For the therapist, the issue should be centered on understanding and listening to other’s experiences, even if they are quite different than our own. Infidelity, communication, and substance abuse are all issues that are common to all couples including homosexual or bisexual couples. However, what differentiates homosexual and bisexual couples from heterosexual couples is the effects of internalized homophobia, societal oppression, and “coming out,” as well as greater fluidity in gender roles (Connolly 2004).

Internalized homophobia is when homosexual or bisexual individuals experience negative feelings and emotions toward themselves when recognizing their own sexuality (Herek 1997). This can bring about feelings of guilt, self-hatred, and negativity regarding the durability of long-term relationships (Ossana 2000). Difficulties in identity formation, identity management, and the “coming out” process can all precipitate from internalized homophobia (Connolly 2004).

Societal oppression comes in two forms: homophobia and heterosexism. Homophobia is defined by any negative belief, reaction, attitude, or action toward homosexuals (Bernat 2001). Homophobia can be hostile due to its inherent discriminatory and prejudicial nature (Connolly 2004). Heterosexism is the belief that heterosexual relationships are preferable and superior to homosexual or bisexual relationships. This belief in and of itself is oppressive (Connolly 2004).

Many persons who are bisexual or whose homosexuality is admitted consciously later in life may spend some years in heterosexual marriages. Many such people are able to function well heterosexually, changing their sexual focus when they realize that “something is missing” or that their level of desire and love is greater for their own sex. Some have low levels of sexual desire in the marriage and develop affairs. Because there may be a great deal of love and affection between the marital partners, the discovery that one member is homosexual is very painful. The desire to remain in the marriage may be strong on one or both sides. Although sex therapy can improve sexual functioning, there is no treatment which has proven effective in decreasing homosexual desires and fantasies. The couple must decide how to handle the situation—that is, whether to divorce, remain in the relationship and allow for alternative sexual behaviors, or whether the homosexual person can remain monogamous in the marriage and give up expressing the other parts of themselves. Therapy can help the couple clarify these alternatives and make decisions. Experience shows that even with the most loving spouses the most common final event is divorce.

Homosexual Civil Unions or Marriages

Homosexual long-term committed relationships have always existed; legalized civil unions or marriages are increasingly common as state laws change. Homosexual and lesbian couples have many of the same issues as heterosexual couples such as struggles over intimacy, power, boundaries and commitment. Some issues particular to such couples need to be noted by the therapist. There is the presence of both external and internalized homophobia, including the ever-present possibilities of legal discrimination, job discrimination and violence. Members of one or both families of origin may not accept the couple as legitimate, so that the couple needs to develop a family of choice. Adding children to the family
becomes complex, requiring adoption or surrogacy for men and the question of sperm donation (and who will carry the child) for women, unless there are already children from previous relationships. Sexual difficulties, in addition to the usual individual and couple issues, may arise from disagreements over monogamy, HIV-related issues, or the tendency of female couples to reduce their sexual frequency. Normal sexual practices of gay and lesbian couples may include a wider variety of activities than those of most heterosexual couples; heterosexual therapists need to be knowledgeable about this. In most ways, however, the same techniques used for heterosexual couples are applicable here.

Sexual Problems after Medical Illness

Adults treated for cancer, diabetes, heart disease, prostatitis, HIV, and chemical dependency may face extraordinary sexual challenges due to the underlying disorder, their treatment, or the illness’ effect on the couple’s relationship. Two separate kinds of problems can occur. In one, the illness specifically affects sexual functioning. For example, surgery for prostate cancer may produce erectile dysfunction. This is now generally treated medically with alprostadil or similar medication in various forms; in few cases penile prosthesis may be necessary. Close communication with the urologist is necessary. The therapist should also help partners expand their repertoire of nonintercourse sexual behaviors. In the second type of situation, sex is still possible but the couple is anxious that having sex will injure one person. The classic example here is sex following myocardial infarction (Cobb and Schaffer 1975). There is no evidence that sex with a known partner in familiar surroundings is problematic for the heart. The very few heart attacks related to sex are most likely to involve affair partners and heavy intake of food or alcohol. The couple should be advised to resume sex as soon as any reasonable exercise is permissible.

Erectile dysfunction may be the predictable side effect of certain antihypertensive medications. Narcotics such as heroin, barbiturates, and alcohol have a similar effect. Obviously, addictive drugs should be stopped or efforts made to change necessary medications. Serious illness of any kind, plus treatment for certain illnesses like cancer, may leave the person with no sexual interest. In this case, the couple may have to live with it, and the therapist’s task is to help the couple decide the best way to handle it within the marital relationship. It is important that the lack of sexual intimacy not end other forms of “comfort touch.” Similarly, surgery, chemotherapy, or radiation for cervical, ovarian, and prostate cancer can reduce desire and performance. HIV and AIDS should alter a couple’s approach to sex, and safe sexual practices must be recommended.

Conclusion

Couples and sex therapy are important forms of psychotherapy. There is little question that developing the skills needed to successfully work with couples presenting with a wide range of difficulties requires an understanding of how normal couples’ relationships change over time, how problems emerge and are maintained, and how focused marital treatment can alleviate distress and dysfunction. The rewards, however, are great when therapists can assist couples in recognizing and shifting the patterns that inhibit their abilities to live rich, intimate lives together. This chapter provides the basics of evaluation and treatment of the most common types of couples. It also succinctly details the kinds of results a therapist might expect and discusses not only when to prescribe couples therapy, but also the practical issues in carrying it out to successful completion.

As mentioned in the introduction to this chapter, long-term relationships that are mutually supportive with a high level of intimacy are rare. As societies around the world (including our own) continue to evolve, unexpected events create havoc even for very stable families. What couples ask of their psychiatrists is the basic knowledge and skills, artfully applied to their joint relationships, to improve the quality of their lives.

References

Hypnosis is a natural state of attentive, focused concentration. As such, most individuals are able to experience trance-like states at different times in their daily lives. An example is the alteration of awareness experienced by some persons as they concentrate intently on a movie or a play while disconnecting from awareness of the surrounding environment. Depending on the degree of natural ability to enter a trance state (hypnotic capacity or hypnotizability), a given subject will require more or less help to enter and use his or her hypnotic capacity. That is, highly hypnotizable individuals enter trance states with ease, on many occasions even without being fully aware of it. Individuals with low hypnotizability require more direction or help from the therapist who facilitates the trance experience. High hypnotic capacity may actually become a liability to patients who are unaware of their hypnotic capacity or of their unconscious use of this mechanism, as is the case of individuals suffering from a dissociative disorder. Even when we do not intend to use hypnosis formally, we must remember that the ability to enter a trance state is widely and naturally distributed throughout the normal population. Thus, some of our patients may be experiencing trance states even without our planning.

Historical Background
The phenomenon of “trance experiences” has been described throughout history. In ancient Greece, trance-like states were used as a vehicle for treatment of mental or physical illness by allowing or facilitating contact with gods or spirits deemed causative of human malaise. Official reports of the use of hypnosis in the modern world date to the 18th century (Table 94–1). Friedrich (Franz) Anton Mesmer (1734–1815) is considered the father of hypnosis. He described the use of “mesmeric passes” (manipulations) by which he believed he was able to influence the “magnetic fluid” throughout his patients’ bodies. Franz Anton Mesmer employed hypnotic interventions as an alternative treatment for many ills that we would now label as stress related or psychosomatic (Lopez 1993). Despite the fact that his work was discredited by a panel of French experts appointed by King Louis XVI (1784), it represented the first Western formal method of psychological treatment, or psychotherapy (Ellenberger 1970). The Royal Commission, headed by Benjamin Franklin (then American ambassador to France), did acknowledge that the phenomenon of suggestion, the influence of one individual on another, was at the root of social order as well as personal change. Now we know that suggestibility not only is one of the main components of the hypnotic experience but also is ever present in any form of therapeutic interaction between physicians of any specialty and their patients.

In the late 18th century, José Custodi Di Faria (1756–1819) proposed the theory of expectancy and receptivity as the clue for hypnotic success. He also moved away from the mesmeric passes to the use of verbal suggestions. During the 19th century, interest in hypnosis persisted in America through the writings of William James (1902), Boris Sidis (Sidis and Goodhart 1905), and Morton Prince (1906), who founded the Journal of Abnormal Psychology. They were fascinated by the extreme symptoms observed in patients with such dissociative symptoms as conversion reactions and multiple personality disorder.

Yet, the use of hypnosis has not been limited to the field of psychiatry. In fact, we owe the name hypnosis to the British surgeon James Braid (1785–1860), who initially coined the name neurohypnology or nervous sleep (Braid 1843), which was later shortened to the current term, hypnosis. The earliest reported use of hypnoanesthesia is attributed to the French surgeon Jules Cloquet, who in 1829 used it while performing a mastectomy (Fourmestraux 1934). In 1836, the first use of hypnosis as an anesthetic in the US was reported in Boston (West 1836). John Elliotson (1843) is credited with the introduction of hypnosis as a form of anesthesia in Great Britain. The British surgeon James Esdaile (1857) reported excellent surgical success rates (up to 85%) using hypnosis as the only form of anesthesia while practicing in India. Throughout the years, the routine use of hypnosis as a form of anesthesia has declined, probably because of the uniformity of results obtained by chemical agents. Nevertheless, the use of hypnosis in medicine has been extended to the treatment of other medical symptoms, including chronic pain and procedural anxiety.

In France, the noted neurologist Jean Martin Charcot (1825–1893) reported cases of patients suffering from pseudoneurological disorders that responded to the use of
History of Hypnosis

Spiegel and Spiegel introduced the Hypnotic Induction Profile specifically designed to assess hypnotic capacity and compartmentalization of memory (Janet 1907). This differed from Freud's model in being horizontal rather than vertical and archiological (Hilgard 1977). According to Janet's dissociative model, information kept out of awareness was relatively untransformed, but it could be accessed directly by use of techniques such as hypnosis. Janet used the ability of highly hypnotizable individuals as evidence of experimentally induced psychiatric illness. Hippolyte Bernheim (1964) took a contrary (and ultimately correct) view that hypnotic phenomena were essentially normal rather than evidence of disease, a viewpoint further developed by Freud's early collaborator Joseph Breuer. Breuer suggested that hysteria was the result of an uncontrolled hypnotic-like state driven by repressed memories and emotions. Later, Breuer and Freud (1955) discovered that these symptoms could be alleviated by asking the patient to talk about these memories and emotions. Thus they began the use of hypnotic age regression or hypnotic reenactment (the "cathartic method") to treat hysterical symptoms. This led to the development of their theory linking unconscious

Suggestion (Charcot 1890). Later, he found that these “hysterical symptoms” could be both induced and removed by hypnosis. Following the steps of his predecessor, Pierre Janet (1859–1947) built a theory of the unconscious involving compartmentalization of memory (Janet 1907). This differed from Freud's model in being horizontal rather than vertical and archiological (Hilgard 1977). According to Janet's dissociative model, information kept out of awareness was relatively untransformed, but it could be accessed directly by use of techniques such as hypnosis. Janet used the ability of highly hypnotizable individuals as evidence of experimentally induced psychiatric illness. Hippolyte Bernheim (1964) took a contrary (and ultimately correct) view that hypnotic phenomena were essentially normal rather than evidence of disease, a viewpoint further developed by Freud's early collaborator Joseph Breuer. Breuer suggested that hysteria was the result of an uncontrolled hypnotic-like state driven by repressed memories and emotions. Later, Breuer and Freud (1955) discovered that these symptoms could be alleviated by asking the patient to talk about these memories and emotions. Thus they began the use of hypnotic age regression or hypnotic reenactment (the "cathartic method") to treat hysterical symptoms. This led to the development of their theory linking unconscious
determinants to conscious symptoms. They believed that “hypnoidlike” states constituted the building blocks of hysterical symptoms. This became one of the first recognitions that hypnotic processes are indeed normal and yet could often be mobilized in the service of resolving an unconscious conflict. Later, as he developed his psychoanalytic theories, Freud (1958) abandoned hypnosis in favor of free association, viewing it as a manipulation of transference phenomena.

During the early part of the 20th century hypnosis was little scientific activity related to the use of hypnosis in clinical settings. Nevertheless, during World War II there was a revival of the technique, as manifestations of the traumas of war required a new treatment approach. Army psychiatrists described the usefulness of hypnotic interventions in treating so-called shell shock syndrome or traumatic neurosis (Kardiner and Spiegel 1947). In the second part of the 20th century investigations in the area of hypnosis ranged from studies of the relationships among hypnotizability, placebo response, and acupuncture, to studies of the differential hypnotizability of patients with psychosis and other psychiatric disorders, to investigations used in determining neurophysiological correlates of the hypnotic state and hypnotic capacity, all with varying success (Alden and Heap 1998, Barabasz and Lonsdale 1983, De Pascalis 1999, Engstrom et al. 1970, Graffen et al. 1995b, Jasiukaitis et al. 1980a, Jensen et al. 2001, Maldonado 1997, Maldonado and Jasiukaitis 2003, Morgan et al. 1974b, Sabourin et al. 1990, Spiegel 1991a, Spiegel and Barabasz 1988, Spiegel et al. 1982, 1985). Novel treatment techniques involving hypnotic manipulations became popular in the 1960s (Erickson 1967a). An era of serious laboratory investigation of the phenomenon began with the development of several hypnotizability scales, such as the Stanford Hypnotic Susceptibility Scales (Hilgard 1965, Hilgard et al. 1958, Weitzenhoffer 1962a, 1962b, Weitzenhoffer and Hilgard 1959). This was followed by the development of several shorter hypnotizability scales specifically designed for use in clinical settings (i.e., Stanford Hypnotic Clinical Scale [Hilgard 1975b] and the Hypnotic Induction Profile [Eliseo 1974, Spiegel and Spiegel 1978, 1987]).

In 1960, the American Medical Association (AMA) and the American Psychiatric Association (APA) officially recognized hypnosis as a legitimate therapeutic tool. Two professional hypnosis societies emerged at the national level, each publishing a journal. The Society for Clinical and Experimental Hypnosis emphasizes research in the field of experimental hypnosis, and the American Society for Clinical Hypnosis focuses more on the clinical applications of experimental hypnosis, and the American Society for Clinical Hypnosis. Two mechanisms involved in the hypnotic process.

**Definition**

Hypnosis is a natural psychophysiological state of attentive, receptive concentration, during which individuals experience a relative suspension of peripheral awareness. Hypnotic phenomena occur spontaneously, but it can be elicited at will. During the context of a therapeutic relationship the alteration of consciousness that hypnotized individuals experience may have a variety of therapeutic applications. The hypnotic experience may be understood as involving three main factors: absorption, dissociation, and suggestibility (Cardena and Spiegel 1991) (Table 94–2).

**Table 94–2 Components of the Hypnotic Process**

<table>

<td>Suggestibility</td>
<td>Involves heightened responsiveness to social cues. It allows subjects to suspend the usual conscious curiosity that makes us question the reason for our actions, making subjects more prone to accept suggestions given no matter how irrational</td>
</tr>
</tbody>
</table>

**Absorption**

By absorption we refer to the tendency or ability of individuals to engage in self-altering and highly focused attention with complete immersion in a central experience at the expense of contextual orientation (Hilgard 1970, Tellegen 1981, Tellegen and Atkinson 1974). As one becomes deeply involved in a central focus of consciousness, one tends to ignore more peripheral perceptions, thoughts, memories, or motor activities. Hypnotized individuals can become so intensely absorbed in their trance experience that they often seem to ignore the environmental context and other peripheral events. This intense exclusion of information that is considered by the subject to be peripheral to the trance state allows the phenomenon known as *trance logic*.

Trance logic implies a thinking pattern that does not obey the rules of “normal” logical processes. For example, it may be suggested that the individual sustain a conversation with a person who is not present in the room. A highly hypnotizable subject may hallucinate the necessary elements of experience without “thinking twice” about the absurdity of talking to an empty chair. An extreme form of pathological absorption is seen in cases of traumatic flashbacks. In these instances, patients become so absorbed in the experience triggered by an environmental cue that they act as though they were reliving the whole experience, despite the impossibility of it.

There is abundant scientific evidence that demonstrates a correlation between hypnotizability and a spontaneous tendency for people to undergo absorbing or self-altering experiences (Tellegen and Atkinson 1974). Therefore, we can assume that individuals who tend to get deeply caught up in external or internal experiences, such as watching a movie or imagining something, that they seem to lose awareness of...
where they are or the context of what they are experiencing may be entering spontaneous trance states and thus may fall in the higher range of hypnotizability. This is because individuals with hypnotic ability may use it spontaneously, not simply when formally instructed to do so. This tendency of highly hypnotizable individuals to enter spontaneous hypnotic states may be a liability to them and may have important interpersonal and clinical implications, as spontaneous trance states may be unwittingly elicited during highly stressful or emotional situations, potentially leading to pathological symptoms (i.e., conversion symptoms and dissociated states) (Barber 1956, Bentler 1963, Duke 1969, Eysenck 1943, Maldonado 2006, Maldonado and Spiegel 2005, 2007).

**Dissociation**

By dissociation we imply the ability to separate mental processes so that they seem to occur independently from each other. The process of dissociation is complementary to absorption. Thus, there is nonpathological and pathological dissociation. During hypnosis, the intense absorption characteristic of the hypnotic state permits keeping out of conscious awareness many routine experiences that would ordinarily be conscious by the process of nonpathological dissociation. When working properly in our daily lives it allows us to carry out several complex tasks simultaneously (e.g., knitting while conversing or watching television).

On the other hand, pathological dissociation may arise as a result of severe trauma or abuse (Maldonado and Spiegel 1994). Even complex emotional states, motor functions, or sensory experiences may be dissociated. Dissociated perception of the internal or external world results in depersonalization or derealization. Restricted access to memory results in cases of dissociative amnesia or dissociative fugue. Motor dysfunction elicited by dissociated phenomena may include cases of conversion disorder, such as conversion paralysis or psychogenic paresthesias. As described by Charcot (1890), most of these phenomena can be both induced and reversed with the structured use of hypnosis.

Dissociated memories may be temporarily and reversibly unavailable to consciousness, but they continue to influence conscious (or other unconscious) experiences and behavior (Hilgard 1977, Kilhstrom 1984). Out of sight does not mean out of mind. Many of the symptoms experienced by patients suffering from posttraumatic stress disorder (PTSD; DSM-IV-TR) (APA 1994) can be explained by the influence exerted by memories unavailable to consciousness. This is the case when a sensory stimulus triggers a flashback in a trauma survivor. The process of absorption complements that of dissociation; the state of intense focal attention (absorption) facilitates putting information outside of conscious awareness (dissociation).

**Suggestibility**

Suggestibility implies the ability to influence someone’s beliefs or behaviors by suggestion. Owing to the intense absorption experienced during trance, hypnotized individuals have a heightened responsiveness to social cues, including suggestions given by the therapist. This enhanced suggestibility allows hypnotized subjects to accept instructions relatively easily. Hypnotized individuals are not deprived of their will, but they do have a tendency to accept instructions in an uncritical way when under trance. This quality of the hypnotic process allows subjects to suspend the usual conscious curiosity that makes us question the reason for our actions. Because of this, hypnotized individuals are more likely to accept suggestions or directions, no matter how irrational they might be. Subjects under hypnosis are less likely to distinguish an instruction coming from an outside source (i.e., from the therapist) from those coming themselves, a phenomenon known as **hypnotic source amnesia**.

This allows highly suggestible individuals to act on another person’s ideas as though they were their own. This aspect of hypnosis may be used by conscientious therapists to bypass the patient’s defenses and mobilize the patient’s strengths. On the other hand, a hypnotized patient is less likely to correct a therapist’s mistakes and may be confused by hypnotic instructions that are vague or misguided.

**Myth Dispelled: What Hypnosis Is and What It Is Not**

Several principles provide guidance for the use of hypnosis in medicine and psychiatry. We attempt to clarify some of the myths and misconceptions about hypnosis by establishing what hypnosis is and what it is not (Table 94–3).

**Hypnotizability is a stable and measurable trait.** Not everyone is hypnotizable. Hypnotizability or hypnotic capacity varies throughout the population. Just as some people have more or less ability to play a musical instrument or no ability at all, there is considerable variation in individuals’ ability to undergo and use hypnosis, and these differences are stable over time (Hilgard 1965, Hilgard and Hilgard 1975, Spiegel and Spiegel 1978, 1987). Hypnotizability is as consistent as intelligence for a 30-year interval in adulthood (Piccione et al. 1989). Hypnotizability is highest in late childhood and declines gradually throughout adulthood. Recognizing this fact is helpful in demystifying hypnosis and reducing anxiety on the part of both the physician inducing hypnosis and the patient. About 75% of the population has some usable hypnotic capacity; of these, about 10% are highly hypnotizable. This means that about one in four adults has no usable hypnotic capacity (Spiegel and Spiegel 2004). It is advantageous to determine this early and encourage those with the ability to use it; other treatment modalities are offered to those who are not hypnotizable.

Hypnosis is something you do with, not something you do to a subject or patient. A therapist inducing hypnosis is in the position of the Socratic teacher, helping students discover what they already know (Spiegel and Spiegel 1978). A useful metaphor to share with subjects is that of a coach. A correctly performed hypnotic induction allows the patient and physician to assess and explore the patient’s hypnotic capacity or lack of it, just as a trainer assesses the athlete’s natural capacities and then attempts to maximize them. This approach tends to minimize power struggles between the physician and the patient. For example, there is less chance of misinterpreting a patient’s inability to experience a hypnotic trance as resistance.

All hypnosis is self-hypnosis. The therapist helps the patient use his or her own hypnotic capacity to undergo a trance state. Helping patients to understand the degree of control they have over their mental processes is a good way to foster mastery and control. By doing this, patients may be able to comprehend the extent to which the unconscious use of their hypnotic abilities may create or contribute to their psychiatric symptoms, as in the case of dissociative disorders (Bliss 1980, 1984a, Spiegel 1974, Spiegel and Fink 1979). Similarly, hypnosis may help patients understand how certain physical symptoms may have unconscious etiological factors, as in the case of conversion phenomena (i.e., psychogenic blindness and pseudoseizures) (Maldonado and Spiegel 2000a) or psychosomatic conditions (i.e., asthma and headache) (Maldonado and Spiegel 2000b).

There are no apparent sex differences in hypnotizability. Men and women are equally hypnotizable (Hilgard 1965, Stern et al. 1978).

Hypnosis is not sleep. The most prevalent misunderstanding derives from the name itself. Unfortunately, in the late 1800s, James Braid coined the word neurohypnology to describe what he considered to be a special kind of sleep (Braid 1843). Later, this was shortened to its current name, derived from the Greek root hypnos, which means “sleep.” The hypnotized individual is not asleep but rather awake and alert. To an outside observer, hypnotized individuals may appear asleep owing to their apparent lack of responsiveness to the environment. This is due to their intense absorption and concentration on their internal experience, rather than due to their lack of will. Similar to a sleeping person, a hypnotized individual has suspended peripheral awareness. Yet, in contrast with what occurs in sleep, the subject’s focal attention is intensely and carefully controlled. Studies show that the power spectral electroencephalogram (EEG) of hypnotized individuals is closer to that of a resting, but alert individual rather than a sleeping subject (Chertok and Kramarz 1959, Evans 1977, Fujisawa 1971, LaRiccia et al. 1985, Shpi’l Berg 1955).

Hypnotizability is not a sign of weak-mindedness. Charcot described the ability to undergo a hypnotic trance as a sign of a defective central nervous system. Today, we know that on the contrary, a hypnotic trance requires an intact capacity for focused concentration. If anything, high hypnotizability is associated with the absence of serious psychotic and neurological disorders (Lavoie and Sabourin 1980, Pettinati 1982, Spiegel et al. 1982).

Hypnosis is not intrinsically dangerous. For the most part, it is a benign process. The same cognitive flexibility that allows patients to enter the trance facilitates their exit from it with clear structure and support from the therapist. The dangers of hypnosis lay not in the process itself but in how it is used. There are few contraindications for the use of hypnosis. An occasional paranoid schizophrenic patient may incorporate an attempt at inducing hypnosis into a delusional system. A severely depressed individual may interpret a failure to benefit from hypnosis as further evidence of little self-worth. These problems can be avoided in part by use of hypnotizability testing at the beginning of the intervention. The most serious problem involves possible effects of hypnosis on memory. This is discussed at length under the section “Forensic Applications of Hypnosis,” later in the chapter.

Hypnosis is not therapy. Entry into a hypnotic state does not have any therapeutic effects of its own, although many find it pleasant and relaxing. Instead, hypnosis is another tool a skilled, trained mental health professional can use to achieve change within the therapy process. Therapeutic change comes not from the state itself but from what happens during it. In this regard, hypnosis is not a treatment itself but rather a facilitator of a variety of treatment strategies. The state of intense concentration elicited in hypnosis can facilitate attention to a variety of strategies that enhance control over somatic function, reduce pain, allow the recovery and restructuring of memories, elicit the reproduction and control of conversion symptoms or fugue episodes, and provide control of dissociated states.

There is nothing you can do with hypnosis that you cannot do without it. As an adjuvant to therapy, hypnosis may help speed the process by which information can be accessed and processed because of its ability to heighten concentration and focus attention; however, it is not a treatment in and of itself.

**Hypnotizability Scales**

Hypnosis is a stable and measurable trait. Given not everyone is hypnotizable to the same degree, it is helpful to perform a clinical assessment of a patient’s hypnotizability before embarking on the use of hypnosis as a therapeutic technique (Spiegel and Spiegel 1987). Most of the hypnotizability scales developed in the early part of the 20th century were designed for use in research settings, most notably the Stanford Hypnotic Susceptibility Scale (Hilgard 1965, Hilgard et al. 1958, Weitzenhoffer 1962a, 1962b, Weitzenhoffer and Hilgard 1959) and the Harvard Group Scale of Hypnotic Susceptibility (Shor and Orne 1962). These scales involve a structured hypnotic induction and an assessment of the subject’s response to a variety of instructions, including alterations in control over movement, sensation, temporal orientation, and perception, such as hallucinatory experiences. Some of the forms have been translated and validated to other languages. The Stanford Hypnotic Susceptibility Scale, From C, had been translated to Italian (De Pascalis et al. 2000) and Spanish (Sanchez-Armass and Barabasz 2005). Meanwhile, the Harvard Group Scale of Hypnotic Susceptibility has been translated to and validated in Australian (Sheehan and McConkey 1979), Czechoslovakian (Svoboda 1989), Danish (Zachariae et al. 1996), Finnish (Kallio and Ihamuotila 1999), German (Bongartz 1985), Romanian (David et al. 2003), Spanish (Lamas et al. 1989), and Swedish (Bergman et al. 2003) populations. Research scales are very accurate and useful in research settings (Angelini et al. 1999, Kumar...
et al. 1996, Younger et al. 2005); on the other hand, they are lengthy, making their frequent use impractical in the clinical setting. Because of these, newer and shorter versions of the same scales have been developed (Bowers 1993, Pekala 1995, Robin et al. 2005).

Over the years, shorter and more practical hypnotizability scales were developed for clinical use, such as the Hypnotic Induction Profile (Spiegel and Spiegel 1978, 1987) and the Stanford Hypnotic Clinical Scale (Hilgard and Hilgard 1975). These scales are briefer (about 5–10 minutes for the Hypnotic Induction Profile and 20 minutes for the Stanford Hypnotic Clinical Scale, compared with 1 hour for the research scales) and are designed for comfortable use even with patients who have severe psychiatric disturbances (Spiegel et al. 1982, 1988, Spiegel and Spiegel 1978, 1987). Clinical scales are well accepted by patients and their use help bypass performance anxiety by shifting the focus of the interaction from one in which the therapist tries to make the patient have a hypnotic experience (i.e., patient’s performance) to one in which the therapist assesses the patient’s response to a set of instructions (i.e., therapeutic intervention) (Spiegel and Spiegel 1987). The therapist focuses on evaluating the patient’s ability to enter the state rather than on getting the person into the state. They all involve a structured hypnotic induction and an assessment of the subject’s response to a variety of instructions, such as alterations in the sense of control over body movements, physical sensations, orientation to time and space, and perception. Furthermore, such a standardized testing induction permits an important deduction regarding the hypnotic capacity of the subject. The restricted range of input from the therapist maximizes the information provided by variations in subjects’ responses. After the results of the testing are discussed with the subject, both can proceed knowledgeably, choosing to use hypnosis or other techniques in the service of an agreed on treatment goal.

The use of this kind of objective measurement has several clinical advantages and therapeutic implications (Table 94–4):

(a) It takes the pressure off both the therapist and the patient. Hypnotizability testing helps to clarify the hypnotic interaction. The therapist objectively assesses the patient’s natural ability to use her or his hypnotic capacity, if any, rather than pushing the patient to respond in a certain manner. By objectively determining the patient’s ability, there is no pressure on the therapist to see whether he or she can hypnotize the patient. Likewise, it reduces the sense of pressure on the patient to either comply or resist. The test setting creates an atmosphere of scientific exploration that encourages rather than coerces involvement.

(b) Hypnotizability testing provides objective data about the patient’s ability to respond to treatment via hypnosis. If the patient is a highly hypnotizable individual, she or he can be rationally encouraged to proceed with the use of hypnosis. Nonhypnotizable individuals can be offered an alternative approach that is likely to be more efficacious, such as relaxation techniques, biofeedback, or medication.

(c) Objective standardized tests of hypnotic capacity used across a large population provide the therapist with scientific data to make rational inferences about the patient’s expected response. Patients’ relative ability, or inability, to restructure their inner experience by hypnosis will provide helpful information to the therapist about the subject’s interpersonal style and/or level of psychiatric disturbance.

(d) The intense concentration and increased receptivity characteristic of the trance phenomenon will make us predict that the capacity to experience hypnosis correlates with responsiveness to psychological treatment. Indeed, research has found a high correlation between high hypnotizability scores and reponsivity to a number of selected clinical problems, such as pain (Hilgard and Hilgard 1975), cigarette smoking (Spiegel and Spiegel 2004), and a variety of medical and psychosomatic conditions (Maldonado and Spiegel 2000b).

The Hypnotic Induction Profile

The Hypnotic Induction Profile (Figure 94–1) (Eliseo 1974, Otani 1993, Spiegel 1977, Spiegel et al. 1976, Spiegel and Spiegel 1978, 1987, Stern et al. 1978) is a useful clinical screening test for hypnotic capacity. It consists of a number of the simple instructions that allow the measurement of patients’ natural ability to tap into and use their hypnotic capacity. It begins with a simple and quick induction, counting from 1 to 3, accompanied by the eye roll. This involves instructed upward gaze and lowering of the eyelids (Figure 94–2). The dissociation between upward gaze and lowering of the eyelid can be scored (Figure 94–3), providing the therapist with an initial, but crude, prediction of the subject’s hypnotic capacity (Hilgard 1981, Sheehan et al. 1979, Spiegel and Spiegel 1978). The eye roll is then followed by a series of instructions to briefly influence the subject’s behavior during and shortly after the test (posthypnotic suggestions). The Hypnotic Induction Profile allows the therapist to rate the subject on five items (Table 94–5) assessing cognitive and

behavioral aspects of the single continuous but brief hypnotic experience elicited during the test. These are (1) ability to experience a sense of dissociation of the left hand from the rest of the body; (2) hand levitation, or floating of the hand back up in the air after being pulled down; (3) sense of involuntariness or unconscious compliance while elevating the hand; (4) response to the cutoff signal ending the hypnotic experience; and (5) sensory alteration in the hand or elsewhere in the body.

Scores on the Hypnotic Induction Profile are significantly but moderately correlated with those on the Stanford scales (Frischholz et al. 1980, Frishholz et al. 1981, Hilgard 1981, Orne et al. 1979, Otani 1993) and provide useful discrimination among different psychiatric disorders, as described in the following section.

### Hypnotizability and Psychiatric Disorders

As we have discussed above, absorption and dissociation are key elements of the hypnotic experience. As it would be expected, research data and clinical experience suggest that certain psychiatric disorders, especially those in which high levels of absorption or dissociative features are present, may be associated with high hypnotizability scores (Table 94–6).

the processes of repression and dissociation allows the victim of PTSD to split into multiple dissociated selves. Some of them suffered the pain and humiliation, while others took on themselves the function of protecting the patient from the experience of further injury. The literature on posttraumatic and dissociative disorders reveals a close relationship between trauma, dissociation, and hypnotizability. The data on DID (DSM-IV-TR) highlights that most patients with DID are highly hypnotizable (Bliss 1984b, Frischholz 1985, Allen and Smith 1993).

Years ago, a syndrome resembling histrionic personality disorder was described (DSM-IV-TR) but in this particular group, the capacity for hypnotic dissociation was deemed to be central. It was labeled the “Grade 5” syndrome (Spiegel 1974). These patients are described to be highly hypnotizable, to repeatedly establish naive and dependent relationships, and to express their distress in dramatic ways. They are slow in becoming aware of their internal cues, requiring much external reassurance. They tend to develop superficial but intense affiliations with new ideas and people that tend not to last over time. Because of their tendency to become overly dependent, they require a therapeutic environment that is highly structured. The goal of therapy with these patients is to help them recognize their tendency to repeatedly seek relationships in which they make themselves vulnerable owing to their tendency to relinquish control.

As in the case of dissociative disorders, several studies described an increased hypnotic capacity in patients suffering from anxiety disorders, especially phobias (Benson et al. 1978, Bodden 1991, Blaustein and Sachs 1985, Braun and Sachs 1985, Braun and Spiegel 1995, 2000a, Spiegel 1984). It is thought that these patients enhanced their natural ability to dissociate by separating themselves from painful physical experiences over time. Later, the same defenses are unconsciously mobilized during periods of extreme anxiety or stress. The same temporary dissociation that allowed the victim to tolerate overwhelming fear and pain earlier in life becomes an ongoing part of the personality structure. This tendency to compartmentalize memories and experiences by similar individuals without PTSD (Stutman and Bliss 1985) or in comparison to psychiatric patients with other disorders (Spiegel et al. 1988). Patients with dissociative disorders (DSM-IV-TR) such as fugue, amnesia, or dissociative identity disorder (DID) (multiple personality disorder) also tend to be highly hypnotizable (Allen and Smith 1993, Bliss 1986, Braun and Sachs 1985, Carlson and Putnam 1989, Braun and Milstein 1986, Frischholz 1985b, Frischholz et al. 1992, Kluft 1985a, 1985c, 1985d, 1985e, 1992, Maldonado and Spiegel 2002a, Putnam et al. 1995, 1996, Spiegel 1984, 1989). Most patients with DID report histories of severe physical and sexual abuse in childhood (Braun and Sachs 1985, Kluft 1985b, Maldonado and Spiegel 1995, 2000a, Spiegel 1984). It is thought that these patients enhanced their natural ability to dissociate by separating themselves from painful physical experiences over time. Later, the same defenses are unconsciously mobilized during periods of extreme anxiety or stress. The same temporary dissociation that allowed the victim to tolerate overwhelming fear and pain earlier in life becomes an ongoing part of the personality structure. This tendency to compartmentalize memories and experiences by

Impulse-control behaviors characteristic of eating disorders (Covino et al. 1994, Evans and Staats 1989, Kranhold et al. 1992) and personality disorders (Baker 1983, Copeland 1986, Murry-Jobsis 1991, Pettinati et al. 1990), especially borderline personality disorder (BP), may represent a state of dissociation associated with higher hypnotizability scores (Maldonado and Spiegel 2005). Some of the common symptoms of patients suffering from eating disorders are strikingly similar to those of patients suffering from some forms of dissociative disorders and include trancelike states during episodes of pathological eating behavior (Pettinati et al. 1985), reliving of the trauma, dissociation, personality disorders (particularly cluster B symptoms), pathological relationship with food, distortion of body image, suicide attempts, and self-inflicted punishment (Molinari 2001, Shearer 1994). Some of the common symptoms of patients suffering from eating disorders are strikingly similar to those of patients suffering from some forms of dissociative disorders and include trancelike states during episodes of pathological eating behavior (Pettinati et al. 1985), reliving of the trauma, dissociation, personality disorders (particularly cluster B symptoms), pathological relationship with food, distortion of body image, suicide attempts, and self-inflicted punishment (Molinari 2001, Shearer 1994). These findings and clinical experience suggest a possible opportunity for intervention employing hypnosis in controlling some forms of disordered eating (Anbar and Savedoff 2005, Gross 1984, 1986, Mantle 2003, Spiegel and Debetz 1978a, 1978b, Torem 1992).

Likewise, many patients suffering from self-destructive behavior described dissociative or trancelike states surrounding periods of self-mutilation (Scagnelli 1980). This is not uncommon among individuals with dissociative and borderline personality disorder (DSM-IV-TR). There is high comorbidity between borderline personality disorder and dissociative disorders (Andersen et al. 1993, Brodsky et al. 1995, Horevitz and Braun 1984, Shearer 1994, Yargic et al. 1998). Studies (Shearer 1994) have demonstrated that high dissociative experiences in patients with BP have been characterized by more self-reported traumatic experiences, posttraumatic symptoms, behavioral dyscontrol, self-injurious behavior, and alcohol abuse. Zanarini et al. (2000) found that compared to control groups, BP patients have much higher levels of dissociation (26% in BP group vs. 3% in controls). Low et al. (2000) found that the frequency of patients engaging in deliberate self-injurious behavior was primarily related to increased dissociation. Wildgoose et al. (2000) studied personality disordered subjects and found that subjects with BP (compared with non-BP, personality disorders) had higher levels of a number of aspects of psychiatric symptomatology, particularly personality fragmentation, most of which were mediated by aspects of dissociation.

Charcot (1890) described a relationship between conversion phenomena and high hypnotizability. He first became fascinated by how the process of mesmerism could reproduce conversion symptoms. Unfortunately, he incorrectly attributed both phenomena (i.e., conversion and hypnotic ability) to a pathological process afflicting the central nervous system. Charcot erroneously concluded that only sick or “hysterical” people could be hypnotized. Later on, others, including Bernheim, Janet, and Breuer, refuted that idea, although all recognized that patients suffering from conversion symptoms were highly hypnotizable (Bernheim 1964, Breuer and Freud 1955, Janet 1907). They attributed the symptoms of conversion to unconscious mechanisms and viewed hypnosis as a tool useful in both the elicitation and the removal of such states. Recent research in hypnosis has been directed at understanding the relationship between hypnotizability and psychiatric illness. More recently, Bliss (1984a) reported that patients with conversion disorder tend to be very hypnotizable, and other studies have corroborated that such patients are more highly hypnotizable than the population at large. These findings have been corroborated by others. For example, Peterson et al. (1950) found that even though only about 20–30% of the general population is highly hypnotizable, nearly 70% of patients with psychogenic seizures exhibit high levels of hypnotizability. Kuyk et al. (1999) also found increased levels of hypnotic susceptibility in patients with pseudoepileptic seizures (PESs) compared with patients experiencing true epileptic seizures (ESs). Finally, Roelofs et al. (2002) found that conversion patients scored significantly higher on hypnotic susceptibility and were more responsive to hypnotic suggestions than were control subjects. He also found a significant correlation between hypnotic susceptibility and the number of conversion complaints presented by patients.

Patients with psychosis, suffering from delusions, loosening of associations, and hallucinations, might be expected to do poorly in tests requiring attention and concentration. Hypnosis represents a state of heightened concentration and focused attention. If these two premises are true, we could predict that severely psychotic patients would not be hypnotizable. Indeed, Copeland and Kitching (1937) made the observation that some previously diagnosed psychotic patients who proved to be hypnotizable had been, in fact, misdiagnosed. Somewhat lower scores have been obtained on the Hypnotic Induction Profile (Pettinati 1982, Pettinati et al. 1990, Spiegel et al. 1982), and a restricted range of scores and the absence of high hypnotizability scores have been found in studies employing the Stanford Hypnotic Susceptibility Scale among schizophrenic subjects (Lavoie and Elie 1973, Lavoie and Sabourin 1973, 1980, Pettinati 1982, Pettinati et al. 1990, Weitzenhoffer 1962b, Weitzenhoffer and Hilgard 1959). The reason for these findings may be that hypnotic responsiveness requires complex cognitive tasks. Actively psychotic subjects (i.e., experiencing delusions, loose associations, and hallucinations) might not be able to adequately focus, thus performing poorly on hypnotizability tests, as they do on many other psychological tests. These findings were independent of psychoactive medication use (Spiegel 1980a). Even though hallucinatory activity can be artificially produced in hypnotic states, psychotic patients, especially those with schizophrenia, have shown impairment in their ability to sustain a high level of attention, which interferes with hypnotic concentration. Patients suffering from a major affective disorder have been found to score between normal subjects and schizophrenic patients in hypnotizability (Spiegel et al. 1982). These findings were independent of psychoactive medication use (Spiegel 1980a).

Thus, several psychiatric syndromes (i.e., schizophrenia, GAD, and to a lesser extent major affective disorder) (DSM-IV-TR) have been associated with generally lower hypnotic responsiveness (Lavoie and Elie 1973, Lavoie and Sabourin 1980, Murry-Jobsis 1991, Pettinati 1982, Scagnelli 1980, Spiegel et al. 1982). It may be that the primary illness process impairs the use of a patient’s natural capacity for hypnotic concentration. Because of this, hypnotizability testing can
sometimes be used to clarify diagnoses. As always, the presence or absence of hypnotic capacity should be interpreted within the context of the presentation, medical and psychiatric histories, and genetic background. In the case of an acute psychosis in which there is no familial background, the presentation is later in life than normal, there is a past history of physical or sexual abuse, and the patient has a high hypnotizability score, a diagnosis of hysterical psychosis or a dissociative disorder should be strongly considered when the possibility of schizophrenia is evaluated (Spiegel and Fink 1979, Steingard and Frankel 1985).

Applications of Hypnosis

General Considerations
Because of the intrinsic qualities of the hypnotic state, it can be an effective adjunct to the treatment of a variety of symptoms and problems, both in psychiatry and in medicine in general. The first criterion to consider is the patient’s level of hypnotizability. Once it has been determined that the patient has usable hypnotic capacity (defined by moderate to high scores in hypnotizability scales), a discussion about the nature of the hypnotic process follows. It is important at this point to dispel any myths and correct misconceptions the patient may have about the process. This includes the cooperative nature of the hypnotic process, rather than the “tell me what to do” most patients expect. Finally, the therapist must decide whether the problem presented by the patient is amenable to hypnotic intervention or whether other steps should be taken instead.

We have divided the discussion of the applications of hypnosis into five areas: general psychiatry, general medicine, psychosomatic disorders, habit control, and forensic psychiatry (Table 94–7).

Application in Psychiatric Disorders

The use of hypnosis in the context of conventional psychotherapy can facilitate the therapeutic process in a number of ways. For example, hypnotherapeutic techniques may be used to enhance the patient’s sense of self, restructure traumatic and phobic experiences, or access to repressed memories that have not emerged with use of other techniques. This is true not only of painfully repressed memories but also of situations in which both the patient and the therapist have worked on resistance issues and feel that some additional leverage is necessary. In conventional psychotherapy, the transference is observed and analyzed; in hypnosis, the transference is used as part of the therapeutic process.

Conventional psychoanalytic psychotherapy involves observation and analysis of the meaning of the transference reaction that arises during therapeutic interactions. On the other hand, when hypnosis is used, transference is not avoided or bypassed but may be amplified. All the usual therapeutic rules and processes of psychotherapy apply when hypnosis is used in the psychotherapy context, which may intensify or accelerate the therapeutic process (see Clinical Vignette 1).

Clinical Vignette 1

A young woman sought consultation with me (JRM) because of a phobia about crossing bridges that had begun 5 years earlier. The patient, a psychiatric nurse, was psychologically minded and despite having seen several therapists for her problem had not been able to resolve it using psychotherapy. The problem was now a major issue in her life because she had just bought a car and was angry that her problem impeded her “new freedom.”

She reported that her phobia initially occurred when she was driving in her sister’s car down a long bridge in one of the coastal eastern states. As she was midway across the bridge, she looked around, noticing that her sister, her sister’s boyfriend, and a cousin were all asleep. She reported becoming slowly anxious. Then, all of a sudden, she became extremely frightened. She slammed on the car brakes and stopped the car in the middle of the bridge. Since then, she has not been able to drive across a bridge again. She proceeded to describe her multiple attempts to do so in the preceding few months.

She agreed to try hypnosis and proved to be an excellent candidate. Her Hypnotic Induction Profile score was 9 out of a possible maximum of 10. After induction of a hypnotic state, age regression was used to return her to the first known episode of panic. It was suggested that she would become both physically and mentally relaxed and then allow her unconscious mind to take her to the first time she ever felt this way. The patient spontaneously curled up in the chair; she began to sob and then scream, “Please, mommy, don’t leave me.”

After the abreaction was over, she spontaneously exited her hypnotic state, and we proceeded to examine and reframe the experience. She reported that under trance, she was able to remember how when she was 7 years of age her mother came home with a box full of plastic bags and began to pack the belongings of each of her children. The mother then put the children and the bags in her car and drove out of town, over the bridge, and into a neighboring state where many of her relatives lived. The patient ended up staying with her grandmother, while her siblings lived (continues)
with two different aunts. She had completely forgotten these facts even though she had always been fully aware that she had been raised by her grandmother.

Still, the question of timing remained. Why did it begin 5 years ago and not before? She closed her eyes and easily entered a hypnotic state. This time she was able to review the events surrounding the initial episode of phobia. She remembered how before initiating her trip down the East Coast, she had arrived home one day and found a message from her long disappeared mother. In it, her mother said that she was going to visit the East Coast and that she intended to visit her and her sisters. The patient contacted her sisters, but their conversation was limited. “Did she also call you?” “Yes,” replied her sister; that was all. She had completely avoided talking or thinking about what was going to happen shortly after her trip. As she was driving over the bridge, noticing that everyone was asleep, her mind began to wander. Fear about what was to happen came to mind. She wished that there was a way by which she could avoid the encounter. Suddenly, she froze. The car stopped and she was unable to continue. She just could not cross the bridge. Once again, she spontaneously excited the trance state and began to provide her own appropriate explanation about what might have happened. She saw this long bridge as a kind of umbilical cord that would reunite her with her mother. Then conflict arose accompanied by feelings of ambivalence and then fear. The only way to avoid the situation was not getting there, and because she was in control of the car, her only way out was to panic, to freeze, and to stop.

After a debriefing session and reframing of her past and how to reinterpret the original trauma as well as the phobia, she expressed feeling confident about her skills as a survivor. She was able to move from being in the position of the indefensible victim (the 7-year-old child) or the handicapped adult and talked about the new challenge that lay ahead. She politely agreed to a plan to test her ability to drive across a bridge. For the third and final time in this session, she entered (now on her own) a hypnotic state and saw herself being able to drive through the bridge. She agreed to return in 2 weeks, after stating that she planned to test herself the following weekend.

Two weeks after the initial contact, the patient returned. She proceeded to recount the events of the three trips she had made by the second session, each of increasing difficulty. To this day, 11 years later, the patient has not had any further episodes of phobia associated with bridges and has an amicable but distant relationship with her mother.

Because of the intense emotions that are characteristic of the hypnotic retrieval (which facilitates expression of inner fantasies), intense feelings and deep personal experiences may be elicited. Some patients may find that the hypnotic state facilitates a sense of infantile dependency in which the therapist becomes the transference object. The quality of this transference reaction will be based on the patient’s early object relations just as in any other therapeutic relationship. Indeed, the transference reaction may develop so fast that the inexperienced therapist may not have the opportunity to recognize it or may do so too late. The difference here is the intensity of the feelings developed as a result of the strong emotions that arise during trance. As in the case of victims of abuse, the therapist may use the transference relationship under hypnosis to foster the patient’s ability to help her- or himself.

An example of this is the use of self-mothering techniques (Sagguelli 1975, Spiegel 1989, 1992, Spiegel and Cardena 1990), in which patients are able to go beyond the anger toward a parent or perpetrator and become able to provide for themselves the nurturing and protection that they needed but never had. The therapist may also use the influence he or she has over the patient to suggest alternative ways to deal with problems. Sometimes a patient recovers a memory under hypnosis but then forgets it once the trance state has ended. The therapist who is aware of this may lead the patient to the goal, always respecting the principle that the patient will remember when she or he is ready to remember.

Another technique is the so-called ego-strengthening technique, in which hypnosis is used to provide positive reinforcement for behavior change (Crasilneck and Hall 1985). Some therapists would provide direct instructions for a symptom to disappear. This authoritarian approach often puts both therapist and patient in an awkward situation; it is unwise to tell a patient something one is not certain to be true, whether or not the patient is in a trance. No one can be certain that a symptom will disappear, even in the case of a highly hypnotizable patient. Alternatively, Milton Erickson (1967) promoted the use of a “therapeutic bind,” mobilizing the patient’s resistance to treatment by intensifying, or “prescribing,” the same symptoms the patient was complaining of. The patient would then construe eliminating the symptom as a victory over the therapist. This approach has the virtue of demonstrating to patients their ability to modulate symptoms, bypassing defensiveness by worsening rather than lessening them (Erickson 1967b).

We recommend a hypnotic approach that emphasizes the educational aspects of the therapeutic experience. It is better to structure the intervention as a lesson in self-hypnosis, which the patient can later employ in the service of symptom reduction, thus recruiting the patient as a partner, rather than a dependent, while at the same time empowering the patient to have a more active approach in health management. This is the main focus of an approach known as hypnotic restructuring (Spiegel and Spiegel 2004). Restructuring in hypnosis involves using the intense state of concentration characteristic of the hypnotic trance to help patients develop a strategy for change that amounts to an affirmation experience rather than a struggle, focusing on “what they are for rather than what they are against.” For example, instead of suggesting that “cigarettes taste bad” or “you will become nauseated when you smoke,” patients use the self-hypnosis exercise to focus on a broader commitment to protect their body in the same way that they would protect a child from poison, viewing their bodies as trusting, innocent creatures that depend on them for their protection. In this approach, mind and body are viewed as distinct but interdependent, and the goal is to change the relationship to the body rather than to prevent smoking. Thus, these patients’ perspective on the problem is enlarged, which makes the resolution of the problem itself an example of a broader pattern of relating to one’s body.

This kind of restructuring strategy can be applied to other problems as well, such as mild-to-moderate overeating (Barabasz and Spiegel 1989), and to the treatment of pain (Brose et al. 1992, Hilgard and Hilgard 1975, Spiegel 1985). In the latter case, patients are taught to transform the pain
signal by making the affected body area colder or warmer, or numb, or to focus on a sensation in some other part of the body. The management of anxiety or panic attacks is not taught by an instruction to relax or not be anxious; rather, patients learn to affiliate with a physical metaphor that connotes relaxation, such as floating in water. In this way, patients can overcome urges or symptoms not by struggling against them but by subsuming them under a commitment to a new way of relating to the body, or through a hypnotically developed capacity to transform sensation (Spiegel and Spiegel 2004).

Finally, we do not use the term hypnotherapist, because there are no hypnotherapists. Instead, there are therapists who use hypnosis within the context of the therapeutic practice to achieve a specific therapeutic result. The difficult aspect of doing hypnosis is not the induction of the hypnosis trance, but what happens once the patient is under trance. Remember that all hypnosis is self-hypnosis. Thus, there are two factors that will predict the success of the hypnosis intervention: the patients’ hypnotizability and the therapeutic skills of the therapist.

Anxiety Disorders
Anxiety disorders are among the most widely prevalent psychiatric disturbances. They afflict as much as 15% of the population (Myers et al. 1984). Anxiety can be seen as a state of hyperarousal experienced by both emotional and somatic discomfort. Patients describe their experience in physical terms, such as palpitations, gastrointestinal discomfort, chest pain, sweating, and motor restlessness. Among anxiety disorders most responsive to hypnotic intervention are panic disorder, phobias, and posttraumatic anxiety disorders. (These will be discussed in the section that follows.)

GAD can be seen as a chronic state of anxiety that usually inhibits psychological comfort and social functioning. GAD involves excessive anxiety, occurring more days than not and lasting over a 6-month period. The anxiety is more like a “free-floating” worry or fear about a number of events or activities and is commonly associated with multiple symptoms, including restlessness, muscle tension, fatigue, insomnia, difficulty in concentrating, and irritability. In contrast, panic attacks are sudden and intense states associated with extreme anxiety and physical and emotional distress, and usually occur in a very discrete period of time. The disorder is usually associated with irrational avoidance behavior and anticipatory anxiety. Studies have shown that patients with GAD have markedly lower scores than do subjects without the disorder (Spiegel et al. 1982).

Whereas, as noted earlier, the hypnotizability of patients with GAD is low, studies show that phobic patients are at least normally and perhaps highly hypnotizable (Frankel and Orne 1976). Phobic reactions involve marked, excessive fear cued by the presence or anticipation of an object or specific situation. Invariably, the exposure to the stimulus provokes an immediate and extreme anxiety response. Hypnosis can be helpful as an adjunctive tool for treating some anxiety disorders because of its ability to help patients control their somatic response to anxiety-provoking stimuli (Brough et al. 1965, Clarke and Jackson 1983, Daniels 1976, Domangué 1985, Erickson 1967b, Foggione 1988, Frutiger 1981, Maldonado and Spiegel 2000b, McGuinness 1984, Morse and Cohen 1983, Scott 1970, Scrignar 1981, Somer 1995, Spiegel et al. 1981b, Stanton 1989, 1993). This enables patients to attend to the stimuli long enough to alter their point of view about them and achieve a sense of mastery over them.

Many case reports and several studies suggest that hypnosis may be an effective adjunct in the treatment of panic attacks and panic disorder (Der and Lewington 1990, Iglesias and Iglesias 2005a, Somer 1995, Stetter et al. 1994, Swartz 1981, Van Dyck and Spinhalov 1997a, 1997b). Similarly, a 7-year follow-up of 178 patients treated with a single session of self-hypnosis for flying phobia indicated that 52% were either improved or cured (Spiegel et al. 1981b).

Most of the strategies in the treatment of anxiety disorders employing hypnosis combine instructed physical relaxation with a restructuring of cognition, using imagery coupled with physical relaxation (Benson et al. 1978, Butler et al. 2005, Daniels 1975, Davidson et al. 1978, Erickson 1967b, Gilbertson and Kemp 1992, Hurley 1980, McCarthy 1967, Meares 1966, Morcas 1984, Smith 1990). As in the treatment of anxiety disorders by systematic desensitization or progressive relaxation, patients are instructed to maintain a physical sense of relaxation (e.g., floating) while picturing the feared situation or stimulus (Marks et al. 1968). It is important that the relaxation instruction uses an image that connotes reduced somatic tension, such as floating or lightness, rather than being a direct instruction to relax. The more cognitive term “relax” may actually induce more anxiety, whereas affiliation with a somatic metaphor usually produces some reduction in tension. Unlike systematic desensitization, hypnosis produces a physically relaxed state that can be rapidly achieved with a quick induction. Also different from systematic desensitization, the coupling of relaxation to a fearful stimulus does not require the development or working through of a hierarchy. A typical self-hypnosis induction can be rapid. For example, a patient can be told,

Now just get as comfortable as you can. There are many ways to enter a state of self-hypnosis. One simple but useful method is to count to yourself from 1 to 3. On 1, do one thing: look up. On 2, do two things: slowly close your eyes and take a deep breath. On 3, do three things: let your eyes relax but keep them closed, let your breath out, and let your body float. Then let one hand or the other float up into the air like a buoyant balloon. This is your signal to yourself and to me that you are ready to concentrate.

Initially, the use of hypnosis in the session can help in demonstrating to patients that they have a greater degree of control over somatic responsiveness than they had imagined. It is often useful to begin by teaching patients to create a place in their mind's eye where they feel safe and secure. On occasion, it helps the subjects to learn how to project their image onto an imaginary screen. Later, they can learn to manipulate the screen by making it either bigger or smaller, having the screen nearer or farther away, as needed:

Just allow your body to float, as if you were floating in a bath, a lake, or a hot tub. Enjoy this sense
of floating lightness. Now, picture in your mind’s eye an imaginary screen. It might be a movie screen, a television screen, or a piece of clear blue sky. First picture a pleasant scene, somewhere you enjoy being.

Allow the patient to experience this state for a minute or two and then inquire about the experience:

With your eyes closed and remaining in this state of concentration, describe how your body is feeling right now. What image are you picturing?

After receiving the answers, add

Notice how you can use your store of memories and fantasies to help yourself and your body feel better.

After they have learned to manipulate the screen and their physical sensations, patients may be ready to do therapy work. They may, for example, learn to re-create the physical state of relaxation while projecting the fearful situation onto the screen. This, then, becomes a useful procedure by which to control and obtain mastery over anxiety-producing situations by dissociating the somatic reaction from the psychological response to the feared stimulus. Initially, the patient is asked to re-create the physical feeling of relaxation. Then, the patient projects onto the screen images associated with the feared situation; only this time the somatic reactions associated with anxiety do not develop. On occasion, it helps for patients to foresee likely physical sensations or situations associated with a fearful experience to master them. For example, in the case of plane phobia, the patient can learn to couple the real sensation of floating in the air with the hypnotic experience: “Learn to float with the plane.”

Patients may also use the trance state as a means of facing their concerns more directly. As in the preceding cases, they may make use of the screen technique (Spiegel and Spiegel 2004). They can achieve this by placing an image of an upcoming performance or fearful situation on one side of the screen, testing out various strategies for mastering the situation on the other side.

Other approaches using hypnosis have included instructing patients in a trance to imagine that they are literally somewhere else, away from the fearful stimulus, thus separating themselves from the anxiety-producing experience (Erickson 1967b, Marks et al. 1968). Positive reinforcement or “ego-strengthening” techniques have also been used; for example, hypnotic instructions are given to patients suggesting that their capacity to master the situation and their response to it will improve (Crasilneck and Hall 1985). There is little reason to use uncovering techniques seeking to link anxiety to some early traumatic experience in cases of phobia or generalized anxiety disorders. This is different in cases of PTSD (DSM-IV-TR), however, in which more work may be needed to confront and place into context the traumatic experience.

Certainly, in some cases, understanding the cause of the feared situation may help resolve the conflict. One of the techniques used to facilitate the recovery of traumatic memories associated with fearful situations is the affect bridge technique (Watkins 1987).

Acute and Posttraumatic Stress Disorder
The use of hypnosis for treatment of traumatic experiences was initially described by Breuer and Freud (1955). At the time, they observed that an abreaction was accompanied by the release of psychic tension and, on occasion, relief of physical symptoms. That was the premise behind the use of the cathartic method. The idea was that some intense affect associated with the traumatic event needed to be released, and that simply repeating the event with its associated emotion in the trance state would suffice to resolve the symptoms. It did not take long for Freud to realize that conscious, cognitive work must be done on the recovered material for it to be successfully worked through (Freud 1946, 1958). Hypnotic techniques for the treatment of posttraumatic conditions were often used by the clinical pioneers of the end of the 19th century and by military therapists treating soldiers during the 20th century’s conflagrations. More recently, hypnosis has also been used with survivors of sexual assault, accidents, and other traumas.

For the psychotherapeutic treatment of trauma victims to be effective, the patient must cognitively recollect the traumatic events with an enhanced sense of control over the memories of the experience; abreaction alone is not enough. The idea is not to reexperience the trauma; patients do that on their own every time they experience a traumatic flashback. In fact, there is actually a risk of further retraumatization in the continuous reliving of traumatic experience without adequate restructuring (Maldonado and Spiegel 1994, Spiegel 1992, Spiegel and Cardena 1990, Spiegel and Spiegel 1987). The cognitive restructuring technique takes the form of a symbolic restructuring of the traumatic experiences under hypnosis and the use of a grief work model (Spiegel 1981). As adapted for the treatment of PTSD (DSM-IV-TR), hypnosis can be used to provide controlled access to the dissociated or repressed memories of the traumatic experience and then to help patients restructure their memories of the events (Maldonado and Spiegel 1994, 1995, Spiegel 1981, 1988, 1989, 1998, Spiegel and Spiegel 1987).

Trauma constitutes a sudden discontinuity in both physical and mental experiences. The effect of the traumatic experience forces the victim to reorganize mental and psychophysiological processes to buffer the immediate impact of the trauma. This process is meant to be an adaptive mechanism to maintain psychological control during a time of enormous stress. Unfortunately, a number of trauma victims go on to suffer acute or chronic symptoms, such as dissociation, intrusive thoughts, anxiety, withdrawal, and hyperarousal, leading to a diagnosis of ASD or PTSD.

There may be a relationship during childhood between stress, such as early trauma, and high hypnotizability. In support of this idea are reports of high hypnotizability in children who were victims of severe punishment during childhood (Nash et al. 1984, Spiegel and Cardeña 1991). It is possible that the impact of the stress suffered encouraged them to use their self-hypnotic abilities more effectively (Kluft 1984, 1992, Spiegel et al. 1982).

The major categories of symptoms in PTSD are similar to the components of the hypnotic process (APA 1994, Maldonado and Spiegel 2002a). Hypnotic absorption is similar to the intrusive reliving of traumatic events experienced by these patients. When in a flashback, trauma victims become so absorbed in the memories of the traumatic event, they lose touch with their present surroundings and even forget that the events took place in the past. Likewise, highly hypnotizable individuals may become so intensely absorbed in the trance experience that they can reenact a previous life event (during hypnotic age regression) as if they were reliving it. A hypnotized patient may dissociate a body part to the extent of not recognizing it as part of his or her body. Similarly, PTSD patients may dissociate feelings to the extent of experiencing the so-called psychic numbing. This allows them to disconnect current affects from their everyday experience in an attempt to avoid emotions triggering memories associated with the trauma. Finally, suggestibility is comparable to hyperarousal. The heightened sensitivity to environmental cues observed in those patients suffering from PTSD is similar to that experienced by a hypnotized individual who responds to suggestions of coldness by shivering.

Because many patients suffering from PTSD are highly hypnotizable (Spiegel et al. 1988, Stutman and Bliss 1985), and because of the resemblance between the symptoms of PTSD and the hypnotic phenomena, it makes sense to use hypnosis in its treatment. Similarly, available reports suggest high hypnotizability in children who were victims of severe punishment during childhood (Nash et al. 1986, Spiegel and Cardeña 1991). Some trauma researchers (Kluft 1984, 1992, Spiegel et al. 1982) have proposed that the impact of the stress suffered during trauma encouraged a more effective use of self-hypnotic abilities, which in turn may enhance or mediate some of the observed symptomatology. If patients suffering from PTSD are unknowingly using their own hypnotic capacities (Kluft 1991, 1992, Maldonado and Spiegel 1994, 2000a, Spiegel 1986, 1988, 1989, Spiegel et al. 1988), it is therapeutically useful to teach them how to enter, access, and control their trance potential. Hypnosis may be invaluable as a tool to access previously dissociated traumatic material.

We do not refer here to uncontrolled abreaction. The purpose is not simply to help the patient remember the trauma, because in a way, every time a patient goes through a flashback, an uncontrolled abreaction is experienced. An abreaction that is not conducted within the context of cognitive restructuring and before new defenses are in place can lead to the further retraumatization of the patient (Kluft 1992, Spiegel 1981).

For therapy of intense trauma to be effective, cognitive restructuring of the traumatic memories must be facilitated along with adequate emotional expression and relationship management. The therapy process must provide an enhanced sense of control over the traumatic memories. This can be facilitated by the process of symbolic restructuring of the traumatic experiences during the hypnotic process (Cardeña et al. 2000, Spiegel and Spiegel 2004), based on the grief work model (Spiegel 1981). Hypnosis can then be used to provide controlled access to the dissociated or repressed memories of the traumatic experience and then to help patients restructure their memories of the events.

Research data support the notion that many victims enter a dissociated state during physical trauma (Bremner, Southwick, and Brett 1992, Butler et al. 1996, Cardeña and Spiegel 1993, Putnam 1985, Spiegel and Cardeña 1991, van der Kolk et al. 1994, van der Kolk and Fisler 1995). If this is the case, it makes sense that enabling trauma victims to enter a structured dissociative state in therapy would facilitate their access to memories of the traumatic experience. The therapy process can help patients work through traumatic memories in order to resolve the posttraumatic symptomatology. The memories can be experienced for a time with the assurance that they can be put aside afterward. In a trance, patients can be quickly taught how to produce a state of physical relaxation despite whatever psychological stress they experience, thereby dissociating the somatic reaction from the psychological preoccupation, allowing for modulation of the traumatic memory and an enhanced sense of control over the experience. Patient and therapist can then find a condensation image that symbolizes some aspect of the trauma.

The most distressing aspect of a traumatic event is the sense of absolute helplessness that it engenders on its victim. This helplessness is reenacted in PTSD through loss of control over state of mind during spontaneous dissociative states, startle reactions, or intrusive recollections of the event. Thus, it is crucial that the therapy of traumatic experiences, especially when such a powerful technique as hypnosis is used, be structured so that the process enhances patients’ sense of control. This approach can allow patients to integrate the image of themselves as victims with the ongoing, more global image of themselves as persons coping effectively with severe stress, making the repressed material conscious and therefore less powerful and enabling them to establish a new, more congruent self-image and absorb the loss into the ongoing flow of their lives. At the end of the following section (Dissociative Disorders), we summarize a comprehensive approach to the use of hypnosis in the treatment of psychiatric syndromes associated with severe trauma.

Dissociative Disorders
Hypnosis is one of the most helpful tools in the treatment of patients suffering from dissociative disorders (Kluft 1992, Maldonado et al. 2000, Maldonado and Spiegel 1995, 2007, Putnam 1992, Spiegel 1986). As a rule, these patients experience their symptoms (i.e., fugue states, dissociated identities, and blackouts) as occurring unexpectedly and beyond their control. Because these patients are unknowingly using their hypnotic capacities, it makes sense to teach them how to turn their weakness into a strength (Maldonado and Spiegel 1995). Hypnosis can be used formally both as a diagnostic tool and for therapeutic purposes. The hypnotic state can be seen as a controlled form of dissociation (Nemiah 1985). Hypnosis is useful in the treatment of these patients, first in...
determining whether they have a dissociative disorder and second is providing rapid access to these dissociated states. When used by the therapist in the context of treatment, it can demonstrate to patients the amount of control they have over these states, which they normally experience as “automatic and unpredictable.”

Thus learning and mastering the hypnotic process not only serves to teach patients how to control dissociation, but it also allows them to establish a process of communication that will eventually lead to a reduction in spontaneous dissociative symptoms. These patients have already suffered physical, emotional, or sexual abuse. Therefore, it is imperative that we recognize and take account of the impact of whatever trauma occurred and help patients work through their reactions to it. Recognizing and teaching patients with dissociative disorders how to master their capacity to dissociate is among the most important psychotherapeutic tasks in the course of their treatment (Maldonado et al. 2000, Maldonado and Spiegel 2002a).

Studies have demonstrated a high frequency of dissociative-like defenses in victims of early childhood abuse, and it is possible that exposure to traumatic events may be one of the natural paths toward developing high hypnotizability. Indeed, studies have shown a positive correlation between severity of punishment during childhood and hypnotizability (Hilgard 1974, Nash et al. 1984, Putnam 1991, 1995). It is possible that the impact of the stress suffered by the victims of childhood abuse allows a more effective use of hypnotic traits naturally found in children. Whether these children do so consciously or not, the frequent use of their hypnotic capacity in an attempt to “avoid” repeated exposure to abuse may prevent its extinction later in life (Morgan et al. 1974a, Putnam 1991, 1995). The unconscious “practicing” of this trancelike trait may account in part for the high level of hypnotizability seen in adults who were once victims of abuse (Kluft 1985a, 1990, Maldonado and Spiegel 1994, 1995, Spiegel et al. 1982).

We can make use of hypnotic techniques as a way to help patients access repressed and dissociated memories. Teaching patients self-hypnosis allows them to obtain a sense of control over their symptoms and eventually their lives. The repression or dissociation of traumatic events and the realities that surround them may serve a defensive purpose of avoiding painful affect associated with the memories. The memories are still there, either transformed or interspersed with fantasy. Our approach to the treatment of these victims is directed at helping them acknowledge the extent of the emotional pain caused by the trauma. Then, through therapy, we can assist in the development of more mature and adaptive coping mechanisms that will allow the patient to place the traumatic experience into proper perspective. The goal is to allow patients to come to terms with the trauma and to redefine themselves in view of the past, but with a firm hold on the realities of the present.

Dissociation as a defense serves a dual purpose. It represents an effort to preserve some form of control, safety, and identity when faced with overwhelming stress. At the same time, victims use it in an attempt to separate themselves from the full impact of the trauma. Unfortunately, these individuals may ward off memories of the trauma so well that they may act as if it is not happening and later as if it never happened. Some individuals can so effectively repress traumatic memories that they become unable to consciously work through them. As a consequence, they are unable to put the facts surrounding the events associated with the trauma into perspective, but slowly, the dissociated feelings and memories leak into consciousness. This creates some of the classic symptoms associated with PTSD and DID, such as flashbacks or intrusive thoughts.

The advantage of using hypnosis comes from the facilitation of the recovery of affect or memories, the ability to dissociate memories from cognition, and the speed with which the process is achieved. Finally, because of the relationship between a history of childhood abuse and trance, these patients are usually highly hypnotizable (Chu and Dill 1990, Hilgard 1984, Nash et al. 1984, Putnam 1993, Spiegel 1988, 1990, Spiegel et al. 1988).

Many former victims of childhood abuse may unknowingly use their hypnotic capacities to keep out of awareness the content of traumatic memories, and in effect create different degrees of psychiatric illness (Sanders and Giolas 1991, Spiegel 1984, 1986, 1989, Spiegel et al. 1988, Terr 1991). Teaching these patients self-hypnosis is a way of turning a weakness into a strong tool for self-mastery and control. The controlled use of hypnosis, then, becomes a way to systematically access previously dissociated material.

A hypnotic-like state may be spontaneously elicited during traumatic experiences. The principle of state-dependent memory teaches us that we store memories along with their associated affect (Bower 1981). If this is indeed true, the experience of a situation with similar affective charge may facilitate the retrieval of the initial memory. While working with hypnosis in the context of psychotherapy, we may elicit memories of a traumatic experience, resulting in the reactivation of the formerly repressed painful affect. The transition into the hypnotic trance can facilitate access to memories related to a dissociated state, as might have happened at the time of the trauma.

The Condensed Hypnotic Approach

The use of hypnosis in the treatment of PTSD and dissociative disorders can be conceptualized as having two major goals, which can be achieved by the use of six different techniques (Maldonado and Spiegel 1994, 1995, 2007, Spiegel 1981, 1988, 1989, 1992) (Table 94–8). The goals are to bring into consciousness previously repressed memories and to develop a sense of congruence between memories associated

with the traumatic experience and current self-images. By making conscious previously repressed memories, the patient has the opportunity to understand, accept, and restructure them. These goals are achieved by working through six treatment stages: confrontation, condensation, confession, consolation, concentration, and control.

First the patient must confront the trauma. The therapist helps the patient recognize and understand the factors involved in the development of the symptoms for which help is now being sought. Hypnosis is then used to help the patient condense the traumatic memories. The hypnotic experience can be used to define a particularly frightening memory during the revision of the patient's history, which summarizes or condenses the main conflicts. The focused concentration achieved during the hypnotic state not only can facilitate recall of traumatic material but also helps place boundaries around it. After memories are recovered, we can help patients restructure them and even "become aware of things you did at the moment of trauma to survive." Once memories are recovered, patients usually need to confess feelings and experiences of which they are profoundly ashamed. These are usually things that they may have told no one else before; in fact, they have been running from them all their lives. At this time, the therapist must convey a sense of "being present" for the patient while remaining as neutral as possible. This is followed by the stage of consolation. Here, the therapist needs to be emotionally available to the patient. This stage must be carried on with caution and in a most professional manner. Therapists should be aware that the body and emotional boundaries of these patients may have been violated in the past. Then comes the stage of concentration. This component of the trance experience allows patients to have access or "turn on" the traumatic memories during the psychotherapeutic session and then "shut them off" once the work has been done. During the final stage, the patient comes to define her- or himself as being in control again.

The underlying principle to remember is that the most damaging effect of overwhelming trauma is that it renders its victims defenseless. Because of the lack of physical and emotional control, patients activate dissociative defenses in an attempt to master their experiences. By using self-hypnosis, the therapist can model and teach the patient to regain control over her or his memories. Patients must be encouraged to remember as much as they feel is safe to remember at a given time. The goal is that patients learn how to think about traumatic experiences, rather than negating their existence. The use of self-hypnosis teaches patients that they are in control of their experiences. Patients must dispel the magical beliefs that therapists "can take away the memories." Rather, by modeling this sense of trust in their therapists, patients learn to trust themselves. They relearn trust in their own feelings and perceptions.

The challenge in treating victims of abuse is to achieve a new sense of unity within the patient after the initial fragmentation caused by the traumatic experience. Overwhelming trauma tends to cause sudden and radical discontinuities in consciousness, which leaves the victims with a polarized view of themselves, involving, on one hand, the old self (before the trauma) and, on the other, the helpless, defenseless, and traumatized victim. Our goal is to find ways to integrate these two aspects of the self. Here, the patient's task is to acknowledge and place into perspective painful life events, thereby making them acceptable to conscious awareness.

One of the advantages of the use of hypnosis is that the affect elicited can be so powerful that most patients do not need to remember every single event of abuse or trauma. In fact, through the use of hypnosis, the therapist may help the patient consolidate the memories in a constructive way, thus facilitating recovery. After a condensation of the traumatic experiences, patients become ready to accept the victimized self. Instead of continuing the self-blame and shame because of what happened to them, they can learn to acknowledge and even thank themselves for what they did to survive. This restructuring allows them to shift their perception of self, changing their self-image from that of a victim to that of a survivor.

**Therapeutic precautions.** Therapeutic precautions are shown in Table 94–9. The strength of transference during the psychotherapy of trauma victims is enormous. The use of hypnosis does not prevent development of a transference reaction; it may actually facilitate its emergence earlier than in regular therapy owing to the intensity with which the material is expressed and memories are recovered (Maldonado and Spiegel 1994, 1995, 2007, Spiegel 1992).

Reliving the traumatic experience along with the patient may allow a special feeling of "being there with them" at the moment of trauma. This allows the therapist to provide guidance, support, protection, and comfort as the patient goes through the difficult path of reprocessing traumatic memories. On the other hand, this kind of traumatic transference between the therapist and the victim of sexual assault is different in the sense that the feelings transferred are related not so much to early object relationships but to the abuser or circumstances that are associated with the trauma (Maldonado and Spiegel 1994, 1995, 2007, Spiegel 1992). Instead of seeing this expressed anger at the therapist as a form of negative transference reaction, we should explore the possibility that this may be a healthy attempt for the patient to experience anger toward the perpetrator. As therapists, we should not minimize or shut off these feelings. This will only confirm the patient's former perception that there was something wrong with him or her for having these feelings, which will probably activate further use of primitive defenses, including dissociation or acting out.

A more serious complication of the use of hypnosis with trauma victims is the possible creation of false memories. Hypnosis, with its heightened sense of concentration, allows the patient to focus intensely on a given time or place, enhancing memory recall. The principle of state-dependent memory also makes it plausible that the mere entrance into this trance state can facilitate retrieval of

memories associated with a similar state of mind that may have occurred during the trauma and subsequent flashbacks. However, not every memory recovered with the use of hypnosis is necessarily true. Hypnosis can facilitate improved recall of true as well as confabulated material (Dywan and Bowers 1983). Suggestibility is increased in hypnosis, and information can be implanted or imagined and reported as verdict (Laurence and Perry 1983, McConkey 1992). Because of this, therapists are warned about “believing” everything a patient is able to recall. Just as we use therapeutic judgment to analyze and interpret our patients’ (nontraumatic) childhood memories, fantasies, and dreams, so should we treat hypnotically recovered material with caution.

To this date, no evidence proves that the patient’s confrontation with alleged perpetrators of childhood abuse or pursuit of legal retribution toward the perpetrator provides any therapeutic benefit. As therapists, we cannot be certain of which memories are real, which are completely confabulated, and which are a combination of both. Because of this, we should not encourage our patients to take legal actions. If, on the other hand, our patients insist in pursuing this avenue, it is our duty to warn them of our concerns but to be supportive of whatever final decision they make. Certainly, we will do a service to our patients if we inform them of all the legal ramifications that the use of hypnosis, or any other form of memory enhancement, may have for their defense, including their ability to testify in court or to use the material recovered by such techniques.

Conversion Disorder
Several studies have suggested that patients suffering from conversion disorders are highly hypnotizable (Bliss 1984a, Peterson et al. 1950). Janet described that the symptoms of conversion disorder can be understood in part as reflecting the presence of uncontrolled hypnotic states (Janet 1907). Maldonado et al. have hypothesized that patients suffering from a conversion disorder may indeed be using their own capacity to dissociate in order to displace the uncomfortable feelings or affects into a chosen part of the body, which then becomes dysfunctional (Maldonado 1996a, 1996b, 1997, Maldonado and Jasiukaitis 2003).

Highly hypnotizable individuals have demonstrated an unusual capacity for psychological control over somatic function. Therefore, it makes sense that hypnotic phenomena may be involved both in the etiology of some somatoform symptoms and in their control (Spiegel and Vermetten 1994). Certain classic conversion disorders such as hysterical paralysis and pseudoseizures may well represent dissociative phenomena, because profound alterations in sensation and experience of control over motor function are standard hypnotic phenomena (Spiegel and Vermetten 1994). Indeed, hypnosis may be useful in both the diagnosis and the treatment of many psychosomatic illnesses and conversion symptoms (Barry and Sanborn 2001, Bowman 1993, Maldonado 1997, Maldonado and Jasiukaitis 2003). Of interest, Goldstein et al. (2000) found that pseudoseizure patients demonstrated higher levels of dissociation and escape-avoidance coping strategies.

In the case of conversion disorders, hypnosis can be used not to remove the process or restore function, but to allow patients to control the effects of their emotional stress and mind states over their body. It is not advised to force a cure in a patient, as this may lead to other complications (e.g., symptom substitution). Instead, patients are trained in the use of self-hypnotic techniques directed at gaining control over physiological and somatic processes and then are allowed to improve at a pace that feels comfortable, while the clinician provides suggestions for improved control and mastery and explores the unconscious psychological reasons behind the presence of symptoms.

Thus, in the case of conversion disorders, hypnosis may have two uses. First, hypnosis may be used to facilitate the accurate diagnosis (Kuyk et al. 1995, 1999, Maldonado 2006, Maldonado et al. 2000, Peterson et al. 1950, Sumner et al. 1952). In fact, during a hypnotic induction the clinician may bring on symptoms, worsen, or ameliorate them demonstrating the psychological responsivity of the symptoms. As already reported by others (Krumholz and Niedermeyer 1983, Ramchandani and Schindler 1993), between 37 and 42% of patients with “true epilepsy” have coexistent pseudoseizures. We must also consider the fact that even though studies have suggested that only 20–30% of the general population is hypnotizable to a somnambulistic level (i.e., highest level of hypnotizability), nearly 70% of patients with psychogenic seizures are capable of reaching the same hypnotic level (Peterson et al. 1950). Given this context, it may be dangerous to assume that hypnotically induced non-epileptogenic events (NEEs) is equivalent to a diagnosis of pseudoseizures (i.e., conversion disorder), as some have suggested (Barry and Sanborn 2001).

Because of the high coexistence of seizures and pseudoseizures and the risks inherent in the misdiagnosis, a quite different use for hypnosis in the diagnosis of pseudoseizures was suggested by Sumner et al. (1952). Instead of eliciting an ictal episode under hypnosis, they proposed the use of hypnosis to elicit memories associated to the time of the seizure itself. In their study, none of the subjects suffering from true epilepsy had any recollection of the events associated with the ictal episode. In contrast, 100% of the patients suffering from pseudoseizure recalled the events. This test had a very high correlation with the EEG data obtained at the time of the ictal activity. Ninety-three percent of those diagnosed as epileptic had abnormal EEG recordings, whereas only 7% of those diagnosed as psychogenic had an abnormal EEG. Nearly half a decade later, Kuyk et al. (1995, 1999) achieved similar results. They studied ESs and patients with PESs, and under hypnosis, which was performed by an investigator who was blind to other data, attempted to recover memories of events, which transpired during the ictal episode. If recall was obtained, the experimental diagnosis of PES was given; if not, ES was diagnosed. These results were then compared with the clinically, EEG-confirmed diagnoses. Hypnotizability was measured in all subjects. They found that recall for the ictus was obtained in 85% of the patients diagnosed with PES. None of the patients with the clinical diagnosis of ES recovered any memories. Fifteen of the patients with PESs reported no memories of the ictal event. This result yields a specificity of 100% and a sensitivity of 85% for the recall technique. They also found that hypnotizability was significantly higher in patients with PESs than in patients with ESs. The authors suggest that a positive recall test indicates PES. As in the case of an EEG, a positive test is positive, but a negative test is inconclusive.
Second, hypnosis may be therapeutic. Such changes in the symptom during or after a trial of hypnosis can be used constructively to teach the patient to utilize self-hypnosis as a means of enhancing control over the severity of the symptom. This hypnotic modulation makes the symptom seem less alien and threatening. Hypnosis can be appropriately used as part of a rehabilitation strategy, particularly insofar as it can help patients master the reactive anxiety that is associated with real physical dysfunction as well as conversion symptoms. A patient can be taught to use a state of self-hypnosis to develop the sense of floating relaxation while picturing bothersome problems on an imaginary screen. The patient can then work on, for example, improving use of a dysfunctional hand by developing tremors that stress the fact that all hypnosis is self-hypnosis, the therapist models for the patient what is expected of him or her by providing suggestions for normalization in sensation and function of the “hypnotized” extremity being used as an example. Patients are then encouraged to use the newly learned skills to restore sensation and/or function—as they did in the office, either in the office with the therapist or “at any time in the future when they felt safe and ready.”

The clinical use of hypnosis in the context of conversion disorder encompasses three phases (Maldonado et al. 2000, Maldonado and Spiegel 2000b). The first phase involves the exploration of the meaning that the symptoms have to the patient. By engaging in this process, the therapist will gain a better understanding of the underlying purpose(s) served by the symptom(s). Two golden rules apply to hypnotic exploration of unconscious symptoms: (1) never eliminate a symptom without understanding first its value and purpose, and (2) never take away a symptom without giving the patient a better (i.e., more mature and adaptive) defense and obtaining the patient’s agreement. The second phase involves symptom alteration. The best form of symptom alteration is one that takes the patients mind away from the presenting symptoms while simultaneously allowing the patient to discover more appropriate ways to cope with their anxiety. This may be accomplished by any one of two symptom-alteration techniques: symptom substitution, in which a given symptom is exchanged for another symptom that is less impairing or pathological until the patient is ready to do away with the symptom (i.e., exchanging the perception of intense pain for a numbings, tingling sensation in the same area); or symptom extinction, in which the patient agrees to “give up” the symptom after working through the problem in psychotherapy. The third phase in the hypnotic treatment of conversion symptoms involves maximizing the patient’s level of functioning. Post-hypnotic suggestions may be quite useful when the patient is very concrete (i.e., not psychologically sophisticated) and in need of constant support or reassurance. Hypnotic techniques can be used as a transitional object while the patient gets on the road of total physical and psychological health (i.e., free of impairing physical symptoms and psychological conflicts). Similarly, the use of projective techniques can become quite valuable in helping the patient to envision him- or herself doing better and living without the illness. At this phase, hypnosis may be used in order to increase the level of motivation, enhance patients’ sense of mastery, and strengthen his or her (ego) defenses.

Maldonado (2001, 2006, Maldonado et al. 2000) described a “reverse symptom identification technique” whereby the therapist, using the positive transference/countertransference in the therapeutic relationship, may mobilize the patient’s healthy defense mechanisms and accelerate the rate of recovery while facilitating a more meaningful exploration of the patients’ symptoms, their significance, and the true etiological reason beneath the symptoms (i.e., the psychological conflict that has been covered or displaced/ converted by the presenting symptoms). Patients are taught how to achieve a state of self-hypnosis and are then hypnotized by the therapist. Following trance induction, the therapist proceeds to produce—in a nonaffected body part, preferably a nonaffected contralateral part—a symptom similar in nature and magnitude to the patient’s presenting symptom. The therapist discusses with the patient the mechanisms involved in the production of that phenomenon. By stressing the fact that all hypnosis is self-hypnosis, the therapist teaches patients that if they can cause the deficit, they will also be able to effect the cure “whenever they are ready to do so, and not before.” Toward the end of the session the therapist models for the patient what is expected of him or her by providing suggestions for normalization in sensation and function of the “hypnotized” extremity being used as an example. Patients are then encouraged to use the newly learned skills to restore sensation and/or function—as they did in the office, either in the office with the therapist or “at any time in the future when they felt safe and ready.”

Eating Disorders

Despite some discordant opinions, there is general consensus establishing that the experience of abuse in early childhood may be important for understanding the complex genesis of the eating disorders of some women (Berger et al. 1994, Molinari 2001, Valdiserri and Kihlstrom 1995a, 1995b). A close analysis of the symptoms demonstrated by eating disorder patients reveal that they are strikingly similar to those of patients suffering from some forms of dissociative disorders. These symptoms include reactualization of the trauma, dissociation, significant personality traits, a pathological relationship with food, distortion of body image, suicide attempts, and self-inflicted punishment (Maldonado and Spiegel 2005).

Studies assessing the hypnotizability of patients with bulimia and anorexia nervosa have demonstrated higher hypnotizability in the bulimic patients than in the restricting patients (Pettinati et al. 1985). These researchers noted that many of the bulimic patients reported that they were in a trancelike state when they engaged in their compulsive bingeing and purging behavior. Researchers (Covino et al. 1994) examined the levels of hypnotizability and dissociation in an outpatient sample of bulimic women of normal weight and compared these levels with...
those of healthy controls. They found that bulimic patients were significantly more hypnotizable than healthy controls and that they scored higher on self-report scales of dissociative experiences. Corroborating these findings, others (Vanderlinden et al. 1995) have found that compared with control subjects, eating disorder patients scored significantly higher on the Dissociation Questionnaire (DIS-Q) and the Stanford Hypnotic Clinical Scale (SHCS). Using semistructured interviews and self-report measures to evaluate the association between childhood physical and sexual abuse researchers compared bulimic women and normal control subjects (Leonard et al. 2003). The study measures assessed eating symptoms, comorbid psychiatric disturbances, personality pathology, and histories of childhood and adulthood abuse. The study found that compared with the normal eaters, bulimic women reported higher levels of childhood abuse.

All these findings suggest a possible opportunity for intervention employing hypnosis in controlling this form of eating disorder (Gross 1986).

**Applications in General Medicine**

**Medical, Surgical, and Dental Procedures**

Because hypnosis can be used to produce a state of relaxation and to reduce anxiety, it has proved to be valuable as an adjuvant to medical procedures (Flory et al. 2007). Once patients have been trained in the use of self-hypnosis, they can use it both in preparation for a hospital visit and while in the clinic or hospital. Once in that state, they can imagine themselves being somewhere they enjoy and feel safe, thereby dissociating their mental experience from the physical (and possibly painful or unpleasant) aspects of the procedure (see Clinical Vignette 2). It can also be used as a way of mastering the anxiety associated with potentially threatening procedures (Rape and Bush 1994), either diagnostic, such as endoscopies (Cavallo et al. 1985, Sutherland and Knox 1976), colonoscopy (Cadranel et al. 1994, Elkins et al. 2006), imaging techniques (i.e., computed tomography and magnetic resonance imaging) (Chandler 1996, Covino and Frankel 1993, Friday and Kubal 1990, Mize 1996, Schulz-Stubner et al. 2004, Simon 1999b, 1999c), bone marrow aspirations (Ellis and Spanos 1994, Hageman-Wenselaar 1988, Liossi and Hatira 1999), needle phobia (Bell et al. 1983, Cyna et al. 2007, Dash 1981, Morse and Cohen 1983, Nugent et al. 1984, Robertson 2007, Simon and Canonico 2001, Usberti et al. 1984), breast biopsy (Montgomery et al. 2002, Montgomery et al. 2007), liver biopsy (Adams and Stenn 1992), and lumbar punctures (Hageman-Wenselaar 1988, Kellerman et al. 1983, Simon and Canonico 2001), or therapeutic interventions, such as chemotherapy (Axelrod et al. 1988, Cotanch et al. 1985, Covino and Frankel 1993, Faymonville et al. 1995, Genuis 1995, Hilgard and LeBaron 1982, Jacknow et al. 1994, Katz et al. 1987, Marchioro et al. 2000, Renouf 1998, Richardson et al. 2006, Syjrala et al. 1992, Zeltzer et al. 1983, 1984, Zeltzer and LeBaron 1982), external beam radiation therapy (Bertoni et al. 1999, Steggle 1999), surgery and its recovery (Kessler and Dane 1996, Lambert 1996), labor, delivery, and post-partum states (Brown and Hammond 2007, Marc et al. 2007, Yexley 2007) and interventional radiology (Lang et al. 1996b, 2000b, Spiegel 2006).

---

**Clinical Vignette 2**

A 43-year-old woman who suffered several episodes of convulsions refused to undergo magnetic resonance imaging (MRI) testing because of feelings of claustrophobia. On two previous occasions she agreed to try, but even after several milligrams of diazepam, she was unable to relax sufficiently to lie comfortably during the procedure. Finally, she accepted a referral to psychiatric consultation. In my office (JRM), she proved to be highly hypnotizable (a score of 9 of 10 on the Hypnotic Induction Profile). During hypnosis, we explored the associations between the scanner and her anxiety. Images of a coffin came to mind. These were then followed by memories of her father lying in the funeral home—he had died of a massive stroke. We then proceeded to explore her anxiety as it related to fears of what the test might show, including the possibility of a malformed blood vessel or other pathological change affecting her brain, as had happened to her father. Once this was discussed, she felt that it “was better to know than to avoid.” She was trained in self-hypnosis. After inducing a relaxed state, she was instructed, “Create in your mind’s eye a place where you can feel safe and comfortable, knowing that sounds and people in the room will not disturb you.” We also “practiced” going to the scanner room by having her imagine that she was the patient in the room and the technician operating the machine. In this fashion, she felt more “in control” of the situation.

The next day, I met her at the scanner room. Once she was on the imaging table, the patient followed the procedure we practiced. When the test began, I left the room with the agreement that the technician would let her know when the test was over. She imagined herself walking through a forest and crossing a river. As she walked to the riverbank, instead of floating, she sank slowly as she followed the contours of the river. On the bottom, she held on to some algae. When she exhaled her breath, it formed a gigantic bubble or cocoon that allowed her to breathe underwater and be safe. As the magnets in the magnetic resonance imager shifted in position, she imagined that this was the clanking sound of motorboat engines on the surface. She remained in this state for approximately 2 hours while tests were performed with and without contrast material. She tolerated the procedure well and easily came out of the trance state when the signal was given.

Pain Control

Pain is always a psychosomatic phenomenon, combining somatic with subjective distress. It never exists in a vacuum and always represents a combination of tissue injury and the emotional reaction to it. James Esdaile (1957), a Scottish surgeon working in India, described 80% surgical anesthesia for amputations with the use of hypnosis. He also reported a lower mortality rate (5%) when using hypnosis for anesthesia in his procedures, compared with the surgical mortality rates in Great Britain (40%), probably because of the high risks of anesthesia or the difficulty of performing surgery without anesthesia at that time. Unfortunately, he later withdrew his findings after being severely censured by his colleagues.

Despite the organic factors causing pain, it is clear that psychological factors are major variables in the intensity of the pain experience. More than 100 years after Esdaile, at the Massachusetts General Hospital, Beecher (1956) demonstrated that the intensity of pain was directly associated with its meaning. For example, to the extent that pain represented threat and the possibility of future disability, it was more intense than it was among a group of combat soldiers to whom the pain of injury meant that they were likely to get out of combat alive.

Hypnosis can facilitate an alteration in the subjective experience of pain (Brose and Spiegel 1992). Several techniques can be used to achieve this goal. Most techniques involve the production of physical relaxation coupled with visual or somatic imagery that provides a substitute focus of attention for the painful sensation.

The specific technique employed may depend on the degree of hypnotic ability of the subject. For example, patients can be taught to develop a comfortable floating sensation on the affected body part. Highly hypnotizable individuals may simply imagine an injection of procaine hydrochloride (Novocain) in the affected area, producing a sense of tingling numbness similar to that experienced in previous dental work. Other patients may prefer to move the pain to another part of their body or to dissociate the affected part from the rest of the body. As an extreme form of hypnotically induced, controlled dissociation, some patients may imagine themselves floating above their body, creating distance between themselves and the painful sensation or experience.

For some more moderately hypnotizable patients, it may be easier to focus on a change in temperature, either warmth or coolness. A sensation of warmth could be elicited while patients imagine they are floating in a warm bath or applying
warmth, or coolness. The presence of such competing sensations as tingling, numbness, and discomfort may serve to “filter the hurt out of the pain.” Patients also learn to transform the pain experience. They acknowledge that it exists (the pain), but there is a distinction between the signal itself and the discomfort the signal causes.

The hypnotic experience that patients create and control helps them transform the signal into one that is less uncomfortable. Patients expand their perception from an experience in which the pain either is there or is not to a third option—the pain is there but transformed by the presence of such competing sensations as tingling, numbness, warmth, or coolness.

Finally, patients are taught not to fight the pain. Fighting pain only enhances it by focusing attention on the pain, enhancing related anxiety and depression, and increasing physical tension that can literally put traction on painful parts of the body and increase the pain signals generated peripherally.

For patients undergoing painful procedures, such as bone marrow aspirations, the main focus is on the hypnotic imagery rather than on relaxation. This works especially well with children because they are so highly hypnotizable and easily absorbed in images (Hilgard and Hilgard 1975, Zeltzer and LeBaron 1982). Patients may be guided through the experience while the procedure is performed, or a given scenario may be suggested, and the patient later undergoes the experience hypnotically while the procedure is under way. This enables patients to restructure their experience of what is going on and dissociate themselves psychologically from pain and fear of the procedure.

Even though the precise mechanism for hypnotic analgesia is not known, it is suspected to have components of two complementary mechanisms: physical relaxation and attention control. Patients in pain tend to splint the painful area instinctively, which in turn increases muscle tension around the painful area, often resulting in increased pain. Therefore, creating a state of hypnotically induced relaxation may easily decrease their experience or perception of pain.

This can be more easily achieved by creating images that facilitate a relaxing response, such as a warm bath, floating on an air mattress in a pool, or just floating out in space. Second, and probably more important, because hypnosis involves intensification and narrowing of the focus of attention, it allows patients to pay selective attention to the action or ideas contained in the metaphor or images, therefore placing pain at the periphery of their awareness. It thus diminishes the amount of attention they pay to painful stimuli. A third possible mechanism affecting the pain experience may be related to the psychological meaning of the pain itself (see Clinical Vignette 3). Some patients have been in pain so long that pain has become an intrinsic part of their existence.

Hypnotic analgesia cannot be explained by simple social compliance alone—merely enacting a role and telling the therapist what he or she wants to hear. Rather, there is evidence that it involves neurophysiological changes in information processing. Studies of the effects of hypnosis on cortical event-related potentials (ERPs) indicate that highly hypnotizable individuals diminish the P100 and P300 components of their event-related response to a somatosensory stimulus by focusing on a hallucinated image that blocks their perception of the stimulus (De Pascalis et al. 2001, Spiegel et al. 1989).

A number of studies have tested the idea that endogenous opiates are involved in hypnotic analgesia. With one partial exception (Frid and Singer 1979), studies with both volunteers (Goldstein and Hilgard 1975) and patients in chronic pain (Spiegel and Albert 1983) have shown that hypnotic analgesia is not blocked and reversed by a substantial dose of naloxone given in double-blind, crossover fashion. Therefore, the cortical attention deployment mechanism is at the moment the most plausible explanation for hypnotic reduction of pain.

Regardless of the underlying mechanism, there is no doubt about the efficacy of hypnotic analgesia. Hypnosis has been shown to be superior to an attentional control condition for analgesia among children undergoing painful procedures (Zeltzer and LeBaron 1982). Furthermore, in a randomized prospective study, a combination of hypnosis and group psychotherapy was shown to result in a 50% reduction in pain among patients with metastatic breast cancer (Spiegel and Bloom 1983). This was accompanied by a significant reduction in mood disturbance (Spiegel et al. 1981a).

Studies have also shown the superiority of hypnotic analgesia to the level of analgesia provided by either placebo (McGlashan et al. 1969) or acupuncture (Knox and Shum 1977). Studies (Study finds hypnosis is more effective 1978, Belshe 2007, Frost 1978, Katz et al. 1974, Kuhn et al. 1981, Li et al. 1975, Loitman 2000, Lu et al. 2001, Moret et al. 1991, Samuels 2005, Stern et al. 1977) have demonstrated a correlation between hypnotizability and responsiveness to acupuncture, proving that hypnotic mechanisms of pain

Clinical Vignette 3

A 62-year-old woman was referred to me (JRM) with hopes that hypnosis would help alleviate her experience of chronic pain associated with cancer. A formal test of hypnotizability demonstrated that she was in the highly hypnotizable range. Under hypnosis, she was instructed that all the pain would “go away,” or at least she would be able to block it, but as soon as she exited the trance state, the pain returned. Because of the curious dynamics of this phenomenon, I decided to explore the meaning pain had for her. She told me how her oncologist had warned her that she would be in pain as long as she is alive. It became clear that she associated pain with being alive and that she would be “pain free” only on the day she died.

After I explored this and discussed it with the patient, she decided that it was “not fair that after suffering so much, I still have to deal with the pain.” She gave herself permission to live without pain and to enjoy as many of her remaining days as she could. She ended her trance experience and discussed it. Shortly afterward, she left the office, inadvertently leaving her cane behind. A few hours later, I called her home to let her know she had forgotten her cane in my office. To which she replied, “You can keep it as a souvenir.”
control may be mobilized by other treatment techniques. Nevertheless, the explicit use of hypnotism with hypnotizable patients has proved to be the most powerful means of controlling pain. Hilgard and Hilgard (1975) estimated a 0.5 correlation between hypnotizability and treatment responsiveness for pain control. However, even older subjects who are somewhat less hypnotizable can benefit significantly (Lutgendorf et al. 2007). It is believed that the ability of highly hypnotizable patients to focus their attention on and alter their response to perception while at the same time producing a physical state of relaxation gives them an unusual ability to restructure their experience of pain, which in turn allows them to develop a sense of mastery over it.

Insomnia
As we discussed earlier, hypnosis is a state of increased concentration and awareness. From this point of view, the hypnotic state is far from sleep, although both are restful altered mental states with reduced awareness of the peripheral environment. So, it might seem paradoxical to use hypnosis to help people fall asleep. Nevertheless, hypnosis can be helpful for inducing a state of physical relaxation that is at least compatible with sleep. As in the treatment of anxiety, a relaxing trance state may diminish the sympathetic arousal usually associated with anxious preoccupation and could facilitate entering into a restful sleep. Patients can be instructed to enter a state of self-hypnosis and then to induce a sense of floating and physical relaxation. Once this is achieved, they may use one of many different mechanisms to put worries or thoughts on hold “for tonight,” knowing that they can always deal with them tomorrow. For example, the patients can project these thoughts onto an imaginary screen. Then they can become a kind of “traffic director” for their thoughts, dealing with them on the screen, thereby dissociating them from the physical response to them while remaining in a quiet and relaxed state (Spiegel and Spiegel 2004).

Another useful method is to have patients imagine themselves lying restfully in a comfortable and safe place while they see themselves placing the disturbing thoughts “onto the clouds, watching the breeze slowly carry them away,” or they can even imagine their worries to be like “leaves floating on the surface of a river, flowing with the current,” rather than holding on to any particular thought. Such approaches can be helpful in conjunction with standard sleep hygiene practices, which include keeping the bedroom as a place to sleep, avoiding working and other anxiety-arousing activities in bed, and avoiding looking at the clock when awakened. It is also important to distinguish routine insomnia due to situational reactions and anxiety from the more severe forms that are associated with major depression, an anxiety disorder, or a sleep disorder, such as sleep apnea syndrome (DSM-IV-TR). Few results of formal studies demonstrating the effectiveness of hypnosis in the treatment of insomnia have been reported, but most case reports suggest that hypnosis is useful in the treatment of not only primary insomnia but other sleep disturbances as well (Bauer and McCanne 1980, Becker 1993, Schenck and Mahowald 1995).

Dermatological Conditions

Specifically, warts have been treated with hypnosis (Ewin 1992a), and one carefully controlled study demonstrated that simple hypnotic instructions to the effect that the warts would tingle and disappear resulted in a rate of improvement that was substantially better than the spontaneous remission rate for warts (Surman et al. 1973). Studies employing hypnosis in the treatment of warts have reported success rates ranging from 27% (Johnson and Barber 1978) to 80% (Ewin 1992a). Other studies have shown specific benefits of hypnosis over simple task-motivating instructions in the elimination of warts (Spanos et al. 1988, 1990). Even more remarkable is Ewin’s (1992a) observation regarding the use of hypnosis in the treatment of warts: “I use the term cure because there is not a single case report in the literature of recurrence after healing with hypnosis.” Ewin reported an 80% cure rate in his study (Ewin 1992a).

Fox et al. (1999) were able to demonstrate the effects of hypnosis in treating patients suffering from frequently recurrent genital herpes simplex virus (rgHSV). Following hypnosis intervention, they recorded a significant overall reduction in the number of reported episodes of rgHSV, accompanied by a corresponding increase in the numbers of CD3 and CD8 lymphocytes, significant rises in natural killer cell counts, HSV-specific lymphokine-activated killer activity, and reduced levels of anxiety when compared to nonimprovers.

Gastrointestinal Disorders

For example, a recent study compared the effectiveness of “gut-directed hypnotic” (6 sessions) and a specially devised audiotape intervention in a randomized controlled trial of irritable bowel syndrome patients during a 12-week study (Forbes et al. 2000). All patients had previously failed to respond to dietary and pharmacological therapy, and their median symptom duration was of 60 months. Successful trance was induced in all hypnotherapy patients. The authors found that symptom scores improved in 76% of the hypnotherapy patients and in 59% of the tape patients. In addition, a reduction in median symptom score, from 14.0 to 8.5, was seen in hypnotherapy patients, compared with an unchanged score of 13 in audiotape patients ($P < 0.05$).

Klein and Spiegel (1989) observed significant hypnotic control of gastric acid secretion among highly hypnotizable subjects. When these subjects were hypnotized and instructed to eat an imaginary meal, basal acid output increased by 89%. In another trial designed to test reduction in acid output, subjects were instructed to use hypnosis to experience deep relaxation. This exercise was accompanied by a 39% decrease in basal acid output. This study highlights the fact that high hypnotizability is a two-edged sword, in that it may increase or decrease a given physiological parameter, depending on the mental content during the hypnotic state.

These observations may have clinical relevance is illustrated by the findings of a controlled trial of hypnosis in relapse prevention of duodenal ulcers (Colgan et al. 1988). In this study patients with rapidly relapsing ulcer disease were randomly assigned, after administration of ranitidine, to hypnosis treatment or no treatment. All of the control subjects but only 53% of the hypnosis patients relapsed. Over the years, several studies have reported the benefits of hypnosis in the treatment of ulcer disease (Bick 1958, Colgan et al. 1988, Francis and Houghton 1996, Montera 1968).

**Respiratory Conditions**

The results of these studies suggest that there is a significantly positive correlation between hypnotizability and treatment responsivity in asthmatic patients. In one such study, Collison (1975) described that one fifth of his asthma patients experienced “complete symptom resolution” and that one third had “considerable improvement in symptoms” after hypnotic treatment and training. In another randomized, controlled trial, after brief treatment with hypnosis, patients with a high hypnotizability score showed marked improvement (74.9%) in the degree of bronchial hyperresponsiveness to a standardized methacholine challenge test and experienced a 26% decrease in the use of inhaled bronchodilators (Ewer and Stewart 1986). In yet another study after brief hypnotic treatment and training, patients reported a two-thirds decline in the number of hospital admissions due to complications of asthma (Morrison 1988). In addition, subjects reported a decreased need for steroid medications, reduced lengths of hospital stay, and overall perceived themselves as healthier. Similar responses have been described in pediatric asthmatic samples (Aronoff et al. 1975, Gluzman and Zisel'son 1987, Kohen 1986, 1987).

These dramatic therapeutic responses to hypnosis are not limited to asthmatic patients. Anbar (2000, 2001) demonstrated that patients suffering from cystic fibrosis may also substantially benefit from the use of hypnosis. These studies demonstrated that patients successfully used self-hypnosis for symptom control 86% of the time. No patient reported worsening of symptoms due to the use of hypnosis. More than 30% of the patients continued to practice hypnosis on their own for 6 months or longer. Many of the patients used hypnosis for more than one purpose, including relaxation (61% of patients), relief of pain...
associated with medical procedures (31%), headache relief (16%), changing the taste of medications to make them flavorsome palatable (10%), and control of other symptoms associated with cystic fibrosis (18%), thus demonstrating that patients can learn to use hypnosis to enhance their control over discomforts associated with cystic fibrosis and its therapy. Similar results have been obtained in the management of chronic dyspnea (Anbar 2001). That is, after 1 month of hypnosis training, 82% of the subjects reported that their dyspnea and associated symptoms had resolved. The remaining patients reported that their symptoms had improved. At a follow-up 9 months after hypnosis training the authors found that there was no recurrence of dyspnea or onset of new symptoms in patients in whom the dyspnea resolved.

Finally, several papers have reported on the use of hypnosis, guided imagery, and biofeedback to help “difficult-to-wean” patients discontinue use of ventilators in the critical care setting (Bowen 1989, Jacavone and Young 1998).

**Applications of Hypnosis in Habit Control**

**Smoking Cessation**

A number of studies demonstrate the efficacy of hypnosis as a tool to facilitate control of smoking. These studies, generally limited to nonrandomized outcome evaluations, show success rates in cigarette abstinence after treatment with hypnosis ranging from 13 to 64%. In some studies, abstinence is strictly defined as no smoking during a follow-up time of at least 6 months (Schwartz 1983, 1987, Schwartz and Dubitzky 1968, 1969). Spiegel (1970) developed a single-session approach for smoking cessation that is widely used. Since Spiegel’s original study, many others have replicated his findings and yielding long-term abstinence rates in the 20–35% range (Berkowitz et al. 1979, Spiegel D et al. 1993, Williams and Hall 1988). Some have developed variations to the single-session method increasing the number of sessions to three (Elkins and Rajab 2004) or five (Watkins 1976). Other case studies have reported abstinence rates as high as 64% at 6 months (Crasilneck and Hall 1985, Holroyd 1980, 1991, Hyman et al. 1986, Schwartz 1987, Williams and Hall 1988), but presumably in highly selected and motivated samples, since these numbers are far better than the rates of unassisted quitting, which are around 10% (Gritz and Bloom 1987). As one would expect, studies have also shown that higher hypnotizability predicts better outcome (Barabasz et al. 1986, Spiegel and Spiegel 1987). Other factors that may affect the outcome in addition to hypnotizability include the presence of external incentives and gender (Agee 1983, Baer et al. 1986, Barkley et al. 1977, Berlin 1980, Cohen 1969, Covino and Bottari 2001, Crasilneck and Hall 1968, Erwin 1977, Frank et al. 1986, Gravitz 1988, Green et al. 2006, Green and Lynn 2000, Holroyd 1980, Hyman et al. 1986, Johnston and Donoghue 1971, Kinnunen 2001, Moses 1964, Pederson et al. 1975, Prokop 1980, Rabkin et al. 1984, Tonnesen and Wennike 1999, West 1977, Wollman 1972).

There are several mechanisms by which hypnosis may contribute to success in smoking cessation. The ritualistic process of the hypnotic exercise may provide a kind of substitute physical relaxation for the “breathing exercise” that accompanies the act of smoking; the positive affirmations in self-hypnosis provide positive reinforcement for behavior change and promote positive self-image; hypnosis enhances self-observation and self-monitoring; and finally it can facilitate cognitive restructuring of the smoking habit.

The single-session method (Spiegel 1970) emphasizes teaching patients self-hypnosis rather than having multiple sessions with a therapist. It uses a strategy that is intrinsically self-reinforcing and meaningful to the patient. It can be practiced whenever the urge to smoke comes on the patient. This method of cognitive restructuring involves emphasizing that the act of smoking is destructive specifically to the patient’s body and thereby limits what the patient can do with his or her life by shortening the life span and deteriorating the quality of life. Hypnosis is used to emphasize the patient’s commitment to protect the body from the poison in cigarettes. This approach gives the patient the ability to examine priorities and to balance the urge to smoke against the urge to protect his or her body from damage. Smokers are instructed to focus on what they are for—protecting their bodies—rather than what they are against—smoking. This reduces the amount of attention they pay to smoking or its absence and provides immediate internal reinforcement for attending to care of the body (Spiegel and Spiegel 2004).

In summary, while the proportion of smokers who become abstinent using hypnosis in some trials is higher than that found with other types of interventions for smoking, there have been no head-to-head comparisons that could determine whether this is due to sample bias or differences in motivation. At the least the limited research literature suggests that techniques facilitated with hypnosis are comparable in effectiveness to other approaches, perhaps because they enable patients to employ a self-administered treatment strategy (self-hypnosis) to reinforce a more adaptive cognitive restructuring while providing patients with an exercise in physical relaxation.

**Weight Control**

The usefulness of hypnosis in the treatment of eating disorders has already been discussed above in the section dealing with psychiatric disorders. Here we cover only the use of hypnosis as a method for loosing weight. Seldom will the use of hypnosis alone be sufficient for the treatment of weight problems. It is usually employed as an adjunct to a comprehensive dietary and exercise control program for weight reduction and management. Similar to the use of self-hypnosis in the control of smoking, the purpose in dietary control is to restructure the patient’s experience with overeating. Patients are asked to examine their excess food intake and to pay attention to the damaging effects to their body. This then translates into an exercise about learning to eat with respect for one’s body. Once again, the emphasis is on what the patient is for, rather than being against food.

An important component of such an approach consists of teaching the patient to use self-hypnosis training to control the urge to overeat. This is better accomplished by preparing a list of food items that constitute eating with respect and then comparing an urge for a particular food item with the list. If the desired food is on the list, the patient is encouraged to eat it like a gourmet, focusing intently on all aspects of the eating experience and enjoying it. If the food is not on the list, the patient is asked to recognize the desire rather than fight the urge. Then the patient is encouraged to
use self-hypnosis to compare this urge with her or his overall commitment to protect and treat her or his body with respect and therefore to eat with respect. This involves dissociating the urge to eat from the need to act on that urge. By using this method, patients can see their desire to eat not as an occasion to feel deprived but rather as one in which they are enhancing their mastery over the urge by choosing to protect their body. Patients are also instructed to pay more attention to their somatic signals of hunger and satiety and to eat when they are hungry, but stop eating as soon as they are full.

Some of the early clinical reports on the use of hypnosis for weight control seemed promising (Bolocofsky et al. 1985, Stanton 1975, Wadden and Flaxman 1981, Winkelstein 1959). Unfortunately, long-term outcome studies on the usefulness of hypnosis for weight control are lacking. In fact, the few systematic reviews of the limited available literature are not very optimistic (Pittler and Ernst 2005) and most have yielded equivocal results (Johnson and Karkut 1996). Clinical experience suggests that those within 20% of their ideal body weight may obtain some benefit from such restructuring techniques with self-hypnosis, combined with a regimen of a balanced diet and exercise. Some have postulated that high hypnotizability is correlated with enhanced weight reduction (Andersen 1985, Deyoub 1979). Barabasz and Spiegel (1989) performed a randomized controlled study comparing the usefulness of hypnosis with a self-management group for weight reduction. All members in the study were highly motivated. The control group was exposed to an active self-management treatment program resulting in adequate weight reduction. On the other hand, the hypnosis subjects were given suggestions emphasizing their desire to protect and care for their bodies rather than to fight the desire for certain foods, along with a behavioral intervention. The results showed significantly greater weight loss among the hypnosis plus behavioral intervention group (mean weight loss, 6.4 kilograms), as contrasted with the group using behavioral intervention only (mean weight loss, 6.4 kilograms), as contrasted with the hypnosis plus behavioral intervention group among the hypnosis plus behavioral intervention group.

The controversies surrounding the so-called false memory syndrome have reignited questions regarding the validity of the material recovered by the use of hypnosis. One of the most common applications of hypnosis in the court and legal settings had been refreshing recollection of witnesses and victims of crimes. Even though the current controversy focuses on the dangers of hypnotically induced confabulation or excessive confidence in memories (Diamond 1980), there have been some positive results. A well-known example is the case involving the driver of a hijacked school bus in Chowchilla, California (1980). Under hypnosis, the bus driver was able to recall the license plate number of the car driven by the kidnappers. This information, not consciously available to him before hypnotic intervention, led to the arrest and conviction of the criminals.

Any memory-enhancing technique has potential problems regarding the veracity of the recovered memories. That also applies to hypnosis. The most serious problem involves possible effects of hypnosis on memory. There is evidence that hypnosis can distort memory in two ways: through confabulation, the creation of pseudomemories that are reported as real, or through concreting, an unwarranted increase in the confidence with which hypnotized individuals report their memories, either true or false (McConkey 1992, Orne et al. 1985, Spiegel 1994, Spiegel and Spiegel 1986, Spiegel and Vermutten 1994). Hypnosis can facilitate the recall of dissociated memories, especially when recall is hampered by the strong affect associated with trauma (Kardiner and Spiegel 1947, Spiegel 1992, Spiegel and Spiegel 1984). However, the research literature indicates that the most clearly reproducible problem is the production of confident errors, exaggerating the true value of memories unearthed in hypnosis.

This is especially a problem when the memories involve witnessing a crime and civil or criminal action in court is a possibility. Most states prohibit the use of hypnotically induced testimony, but some prescribe witnesses who have been hypnotized regarding the content of their potential testimony (Spiegel and Scheflin 1994). If the possibility exists that a patient may be required to testify, it is wise to discuss the use of hypnosis with the patient and (with the patient’s permission) the patient’s attorney or the district attorney and obtain written agreement regarding its use. If the patient is likely to be called to testify, the therapist should obtain electronic recording of all contact with the patient (preferably on videotape) so that the court can examine for possible suggestive influences. Full guidelines for use of hypnosis in the forensic setting include careful debriefing of the subject before hypnosis is employed, the use of nonleading questions, complete videotaping of all contact with the patient, and careful debriefing afterward (Maldonado et al. 2000, Scheflin and Spiegel 1998, Spiegel and Spiegel 1986).

In the forensic setting, hypnosis could have a number of practical applications, but the one that is more common and potentially problematic is the use of hypnosis for the purpose of refreshing the recollection of both victims and witnesses (Gravitz 1995). Several widely popularized cases, like the Chowchilla school bus hijack and the use of hypnosis to enhance the recollections of the driver that led to the recovery of the children kidnapped and the capture of the perpetrators, have increased its popularity as a method for memory enhancement (People v Schoenfeld 1980). Unfortunately, it has helped cement a long-standing misconception regarding the use of hypnosis as a truth serum.

Applications of Hypnosis in the Forensic Setting
In the forensic setting, hypnosis could have a number of practical applications, but the one that is more common and potentially problematic is the use of hypnosis for the purpose of refreshing the recollection of both victims and witnesses (Gravitz 1995). Several widely popularized cases, like the Chowchilla school bus hijack and the use of hypnosis to enhance the recollections of the driver that led to the recovery of the children kidnapped and the capture of the perpetrators, have increased its popularity as a method for memory enhancement (People v Schoenfeld 1980). Unfortunately, it has helped cement a long-standing misconception regarding the use of hypnosis as a truth serum.
Hypnosis and Forensic Psychiatry

Spiegel (1980b) described what he called that hypnosis increases the recovery of memories, both true and confabulated. A good guideline is that hypnosis can amplify both truth and falsehood. A good guideline is that hypnosis increases the recovery of memories, both true and confabulated. Spiegel (1980b) described what he called the “honest liar,” a hypnotized witness who in his or her desire to please the hypnotist or simply as a result of being in the suggestible state of hypnosis makes up material and believes the newly created story to be real. This poses obvious dangers for the legal system. A witness who produces “confident errors” (McConkey 1992) may mislead a jury looking for signs of discomfort or insecurity in their evaluation of the veracity of testimony. This has been termed concreting (Diamond 1980, Orne et al. 1979).

On the other hand, people do dissociate during trauma, often failing to recall events despite being conscious at the time (Cardeña and Spiegel 1993, Spiegel and Cardéa 1991). There is evidence that such memory gaps may persist for years or even decades after such traumatic events as physical or sexual abuse (Williams 1994). Therapists treating victims of sexual abuse must be aware that the use of hypnosis may compromise the ability of a witness to testify in court. Indeed, several states, including Arizona (State ex rel Collins v Superior Court 1982), California (People v Guerra 1984, People v Shirley 1982), New Jersey (People v Hurd 1982) (Cox and Mackay 1982), and New York (People v Hughes 1983) restrict the testimony of victims or witnesses who have used hypnosis to refresh their recollection. The reason for the courts’ objection to the use of hypnosis is a combination of real and exaggerated dangers of hypnosis.

Researchers conducted a meta-analytic review of 24 research studies dealing with the recall accuracy for hypnotized vs. nonhypnotized eyewitnesses in forensically relevant settings (Steblay and Bothwell 1994). They found that the recall accuracy for nonleading questions after a 1- to 2-day delay favored the hypnotized subjects ($d = 0.46$); however, less accurate recall was evidenced for hypnotized subjects following a delay of less than 24 hours ($d = -0.29$) or a 1-week delay ($d = -0.24$). As expected and theorized by many memory and hypnosis experts, the recall of hypnotized subjects also displayed more intrusion of uncued errors and higher levels of pseudomemory. Also expected was the finding that hypnotized subjects also expressed higher levels of confidence in recall accuracy compared to nonhypnotized subjects. These findings have urged caution to be used when dealing with hypnotically refreshed memory.

Some legal commentators have argued that testimony derived from hypnosis should not be allowed as evidence in a court room because of its inherent unreliability and the unduly powerful impact it may have on a jury. Nevertheless, research using a jury simulation technique designed to study the impact that a hypnotically refreshed witness has upon jurors’ decision making found that jurors view hypnotic testimony with a certain amount of skepticism (Greene et al. 1989). The researchers concluded that the impact of witnesses who have undergone hypnosis is comparable to that of testimony based on delayed recall, and rarely does it have the impact of testimony from an immediate report. Of interest, they found that jurors’ judgments about hypnotically refreshed testimony affected the way they evaluated other evidence at trial. For example, jurors who learned that a prosecution witness had been hypnotized were less believing of other prosecution witnesses than were jurors not exposed to hypnotic testimony.

After much legal battling, some courts now allow witnesses to testify after the use of hypnosis provided that certain guidelines are followed (California Legislature 1985). These primarily relate to the training and independence of the professional doing the hypnotic interrogation and the electronic recording of the entire process (Spiegel and Spiegel 1986).

To address this controversial issue, the Council on Scientific Affairs of the American Medical Association convened a panel of experts to examine the research evidence relevant to this problem. The report issued by the panel concluded that the existing evidence indicates that the use of hypnosis tends to increase the productivity of witnesses, resulting in new memories, some of which are true and some of which are incorrect (Orne et al. 1985). Furthermore, some studies showed an increase in the confidence assigned by hypnotized subjects to their memories despite the fact that their percentage of correct responses had not improved. The panel noted that the analogy between the laboratory setting in which most of the studies were done and the real-life situation in the courtroom must be drawn with great caution and that situations in which extreme emotional and physical trauma had occurred differ markedly. The panel recommended that careful guidelines similar to the ones adopted by the state of California be followed when hypnosis is used in the forensic setting (Table 94–10).

As a rule, it is advisable to caution attorneys and witnesses that the use of hypnosis might open the possibility of challenge to the credibility or even the admissibility of a witness. The kind of situation in which hypnosis is most likely to be worth the risk is one in which there is a traumatic amnesia for the events of a crime or in which all other avenues of exploration have been exhausted. Hypnosis is by no means a truth serum, and the courts must weigh the effects of any hypnotic procedure on a witness.

### Table 94–10 Hypnosis and Forensic Psychiatry

If you consider the use of hypnosis in a trial case, certain guidelines need to be observed:

- Caution attorneys and witnesses that the use of hypnosis might open the possibility of challenge to the credibility or even the admissibility of a witness
- Carefully document memory before hypnosis of the witness
- Use an expert psychiatrist or psychologist as a hypnosis consultant
- Electronically record all interaction preceding, during, and after hypnosis sessions. Document and record all contact with the victim
- Conduct the interview in a neutral tone. Guide the victim through the experience but avoid using leading or suggestive questions. Avoid introducing information during the interrogation
Because it is almost impossible not to add some degree of contamination to the procedure, we recommend that at least the following steps be undertaken. First (with the patient’s permission), consult with the victim’s attorney. If an investigation is in progress or court proceedings are likely, you may also want to contact the district attorney’s office or the police. Second, make a video (preferably) or audio recording of all contact with the victim. Make certain that you can clearly hear the voice of the victim and your own voice or that of anyone else participating in the process. Third, conduct the interview in a neutral tone. Guide the victim through the experience but avoid using leading or suggestive questions. It is imperative to avoid introducing information during the interrogation. This is best achieved by asking open-ended, neutral questions based on the information already provided by the victim. For example, ask questions such as “Now what is happening?” rather than “Did he knock you down?” or “Who raped you? Was it your father?”

The medico–legal aspects of the use of hypnosis in psychiatric practice have already been discussed at length elsewhere (Maldonado and Spiegel 2002, 2007, Spiegel and Spiegel 1986).

**Neurophysiological Correlates of Hypnosis**

Since the earliest days of hypnosis, scientists have been trying to understand its neurophysiological underpinnings. Mesmer initially explained the mechanism of action of his technique as the manipulation of the body’s energies, or magnetic fluid. In the late nineteenth century, Rudolf Heidenhain explained hypnosis physiologically in terms of cortical inhibition (Windholz 1996). By the beginning of the twentieth century, Pavlov provided a new model, suggesting that hypnotic states could be understood in terms of partial inhibition of the cortex (Windholz 1996). Subsequently, the debate regarding the mechanisms mediating the hypnotic phenomenon continued between Charcot (1890), who described hypnosis as a disease of the nervous system and argued that normal people could not be hypnotized, and Bernheim (1964), who challenged Charcot’s ideas of hypnotizability as a disease and rather described it as a trait exhibited to different degrees by normal individuals (Widlocher and Dantchev 2002a, 2007, Spiegel and Spiegel 1998).

Since those early times, many research efforts have attempted to correlate the hypnotic experience with actual physiological changes. To date, a “seat of hypnosis” has not been found in the brain, although recent research points toward involvement of the frontal and anterior cingulated cortex (Kropotov et al. 1997, Rainville et al. 2002, Spiegel 2003). There is ample clinical and research experience indicating that the hypnotic process affects both electrical and metabolic processes in the brain. Similarly, as we have observed in clinical experience, hypnotic activity is capable of causing various physiological changes. Some of these have been simulated under laboratory conditions.

The ability of highly hypnotizable individuals to control peripheral skin temperature and blood flow has been replicated in several well-controlled experiments (Grabowska 1971, Kistler et al. 1999, Zimbardo et al. 1970). Conn and Mott (1984) demonstrated plethysmographic measure changes caused by hypnotically mediated rapid vasodilatation after direct suggestion in cases of Raynaud’s disease treated with hypnosis.

Gemignani et al. (2000) studied the physiological and electroencephalographic responses of highly hypnotizable volunteers suffering from simple phobia. Under hypnotic suggestion, subjects exposed to aversive stimuli experienced significant increases in heart rate (HR) and respiratory rate (RR) with a shift of the sympatho–vagal indexes toward a sympathetic predominance. These subjects also experienced a significant increase in the EEG gamma band with left frontocentral prevalence.

Finally, Williamson et al. (2001) using healthy, highly hypnotizable volunteers demonstrated dramatic changes in ratings of perceived exertion (RPE) when asked to imagine themselves in an uphill bicycle grade. They found significant increases in RPE, HR, mean blood pressure (BP), regional cerebral blood flow (rCBF) in the right insular cortex, and right thalamic activation. Conversely, when subjects were asked to imagine themselves on a perceived downhill grade, they observed decrements in the ratings of both RPE and rCBF in the left insular cortex and anterior cingulate cortex, but it did not alter exercise HR or BP responses.

**Neurotransmitters**

Hypnotizability has been found to be significantly correlated with cerebrospinal fluid levels of homovanillic acid, a metabolite of dopamine (Spiegel and King 1992) (Table 94–11). This provides evidence for the involvement of the frontal cortex in the hypnotic process because levels of homovanillic acid in the cerebrospinal fluid primarily reflect activity in the frontal cortex and basal ganglia, which are rich in dopaminergic synapses. Some have suggested that the administration of dopaminergic agents such as amphetamine may enhance hypnotizability (Sjoberg and Hollister 1965). It has been postulated that the automaticity observed in hypnotic motor behavior could represent an activation of the basal ganglia, which is involved in both implicit memory (Graf and Schacter 1985, Mishkin and Murray 1994, Schacter 1987, 1992) and routine motor activity.

**Brain Electrical Activity**

Even though it was initially described as a form of nervous sleep, today we know that hypnosis and sleep share no common characteristics. The brain electrical pattern of a hypnotized subject actually resembles that of a fully awake and attentive individual more than the pattern of a person...
who is asleep (see Table 94–11). Power spectral analysis of brain electrical activity has provided some limited understanding into the physiological mechanism of the hypnotic state. More recently, Fingelkurts et al. (2007) hypothesized that alteration in functional connectivity of the brain may be regarded as a neuronal correlate of hypnosis (at least in very highly hypnotizable subjects) in which separate cognitive modules and subsystems may be temporarily incapable of communicating with each other normally during the hypnotic state.

Various researchers (Edmonston and Grotevant 1975, Morgan et al. 1974b) have reported an increased alpha activity among highly hypnotizable individuals. This difference is present whether or not the subjects were in trance. They also found an alpha laterality difference favoring the left hemisphere among highly hypnotizable individuals. This difference suggested that hypnosis might preferentially involve the right cerebral hemisphere, because alpha is the noise the brain makes when resting but alert, so relatively less alpha on the right suggests more activity. These findings are supported by observations that highly hypnotizable individuals tend to be left-lookers, preferring to activate their right hemisphere (Bakan 1969, Gur and Reyher 1973). Finally, Meszaros and Szabo (1999) demonstrated that in highly susceptible subjects the right parietotemporal region shows more electric power than the left one, while the low susceptible subjects have left-side predominance or equilibrated power in all derivations.

Other studies have questioned the right hemispheric dominance theory of the hypnotic process. Edmonston and Moscovitz (1990) obtained bilateral EEG measures on highly hypnotizable subjects while performing hemisphere-specific tasks during hypnosis and no-hypnosis control conditions. These studies suggest a lack of task-appropriate activity during hypnosis, indicating that data analysis techniques were the source of potential misinterpretations of previously obtained data.

Jasiukaitis et al. (1997b) raised new questions regarding the old theory of right-cerebral-hemisphere dominance of brain activity during hypnosis. They conducted a review of the literature and included in their analysis data from electrodermal responding, visual event-related potentials (VERPs), and Stroop interference. Their analysis suggests, instead, that although hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge might involve, several general aspects of hypnosis might be more appropriately seen as left-hemisphere rather than right-hemisphere brain functions, including concentrated attentional focus and the role of language in the establishment of hypnotic reality.

There may also be frontal vs. posterior topographical differences among high and low hypnotizable individuals. In fact, more recent studies of power spectral analysis suggest that theta power, especially in the frontal region, best differentiates highly hypnotizable from poorly hypnotizable individuals (Sabourin et al. 1990). Similarly, Graffin et al. (1995a) found greater theta power in the more frontal areas of the cortex for highly hypnotizable subjects. During the actual hypnotic induction, theta power increased markedly for both groups in the more posterior areas of the cortex, whereas alpha activity increased across all sites. In the period just preceding and following the hypnotic induction, poorly hypnotizable subjects displayed an increase in theta activity, whereas highly hypnotizable subjects displayed a decrease. Taken together, these findings suggest that anterior/posterior cortical differences may be more important than hemispheric laterality for understanding the hypnotic processes.

ERPs have been used to study the effects of hypnotic hallucination on brain electrical activity. These studies are based on the premise that hypnotically induced changes in perception should be reflected in alterations in ERP amplitude. The results of early studies showed varying and contradictory effects. Halliday and Mason (1964) and Amadeo and Yanovski (1975) found no effect of hypnotic hallucinations on the EEG, but studies by others (Clynes et al. 1964, Wilson 1968) did. These studies were limited because of small sample sizes, nonquantitative analysis of EEGs, limited use of hypnotizability testing, and use of subjects with comorbid neurological or psychiatric disorders.

On the other hand, evidence suggests that highly hypnotizable subjects experiencing a hypnotic hallucination may alter their perception of an external stimulus with corresponding amplitude changes in the response evoked to an external stimulus (Clynes et al. 1964, Wilson 1968). Some have found that highly hypnotizable subjects who experience a visual hallucination obstructing their view of a monitor showed significant reductions in P300 amplitude throughout the scalp and of N200 in the occipital region (Spiegel et al. 1985). This alteration occurred only in highly hypnotizable subjects in which a hallucination was suggested. It was not seen in any other hypnotic condition, and it was not evident among a group of subjects with low hypnotizability attempting to experience the same perceptual alteration.

Jasiukaitis et al. replicated these results (Spiegel et al. 1985) with visual hypnotic obstruction but included an additional condition in which highly hypnotizable subjects were instructed to simply ignore half of their visual field (selective inattention) outside of the hypnotic trance. Both hypnotic obstruction and selective inattention reduced P100 and P300 peaks of visual evoked potential (Figure 94–4). However, the P200 peak differentiated hypnotic from non-hypnotic conditions. Hypnotic obstruction decreased P200, whereas selective inattentiveness actually increased it. These results suggest that subjects performing positive hypnotic hallucination employ, to a degree, elements of inattention along with processes unique to hypnosis. Later, new visual ERP research implicated the left cerebral hemisphere in hypnotic perceptual alteration (Jasiukaitis et al. 1996). This study found a greater reduction of occipital P200 amplitude during hypnotic obstructive hallucination when visual stimuli were presented to the right visual field than when they were presented to the left visual field, which demonstrates a stronger hypnotic effect of imagery in the left than the right occipital cortex.

The effect of auditory hallucination has been studied with similar results. Sigalowitz et al. (1991) found P300 differences among highly hypnotizable individuals hallucinating a reduction or increase in tones; subjects with low hypnotizability did not show such a change. The amplitude reduction did not reach statistical significance, but the increase during positive hallucination did. Crawford et al. (1996) studied the effect of hypnotic susceptibility levels on auditory event-related potentials (AERPs) and found that high hypnotizable
individuals appeared to divert greater attentional processing to the tasks at hand and were also slower to respond to not-to-be-attended stimuli. These findings confirmed the hypothesis that hypnotic susceptibility is associated with efficient attentional processing such that high hypnotizable individuals can more effectively partition attention toward relevant stimuli and away from irrelevant stimuli than can low hypnotizable individuals. Lamas and Valle-Inclan (1998) found that there were increases in reaction times and P300 latencies as a function of noise and spatial stimulus–response incompatibility (Simon effect), and that hypnotic suggestions decreased the response times for all types of trials nonsignificantly indicating a specific effect of hypnotic suggestions in the processing of hallucinated stimuli, which is consistent with the hallucinatory experience reported by the subjects.

A study by Barabasz et al. (1999) examined the effects of positive obstructive and negative obliteratoring instructions on simultaneous VERPs and AERPs—P300 signals. Subjects were selected on the basis of high and low hypnotizability and were requested to perform identical tasks during waking and alert hypnotic conditions. The study found that highly hypnotizable subjects showed greater ERP amplitudes while experiencing negative hallucinations and lower ERP amplitudes while experiencing positive obstructive hallucinations, in contrast with low hypnotizable subjects and their own waking imagination-only conditions. These results constitute a rather robust physiological marker of hypnosis, an alteration in consciousness that corresponds to participants’ subjective experiences of perceptual alteration.

Hypnotically induced hallucinated experiences in other sensory modalities have yielded similar results. Similar to the use of hypnosis for pain control, hypnotic suggestions given to filter somatosensory (electrical) stimulation applied to peripheral nerves affect ERP amplitude. Suggestions of a tingling, cool, numbing sensation were given with the idea that it would filter out any other sensations in the area. This approach produced a significant reduction in P300 amplitude and also in P100 amplitude, suggesting earlier filtering of the somatosensory signal in the hypnotic hallucination condition. The interpretation of these data suggests that these subjects responded cortically as though the stimulus were less intense. When suggestions to increase attention to the stimuli were given, a significant increase in P100 but not in P300 amplitude was observed. This is further evidence that highly hypnotizable subjects were capable of producing bidirectional changes in ERP amplitude to sensory stimuli, depending on the cognitive task employed during hypnosis (Spiegel et al. 1989). Subjects with low hypnotizability or volunteers trying to simulate these conditions were not able to reproduce these findings. De Pascalis and Carboni (1997) studied somatosensory target selection in women and found that highly hypnotizable subjects demonstrated significant suppression of P3 peak amplitude to target stimuli in the left frontal and posterior scalp sites during hypnotic obstructive hallucination as compared to a normal attention condition. The researchers concluded that hypnotically induced obstructive hallucination to somatosensory stimuli involve alterations in neural and autonomic responses that are consistent with a trait conception of hypnotizability. Crawford et al. (1998) studied the somatosensory responses under hypnotic analgesia of moderate to highly hypnotizable adults with chronic low back pain. They found that hypnotic analgesia led to highly significant mean reductions in perceived sensory pain and distress, suggesting that this was an active process that required inhibitory effort, dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of thalamocortical activities.

In a related topic, the somatosensory event-related potential (SERP) literature (Naatanen and Michie 1979) demonstrated the presence of a clearly defined response to SERP’s selective attention, evidenced by a negative deflection 140 milliseconds after the stimulus was administered, known

---

**Figure 94–4** Grand mean (N = 22) visual evoked potentials to right visual field stimuli at electrode T5. (Top) Dark waveform is the visual evoked potential while the visual field is attended. Light waveform is the visual evoked potential while the right visual field is not obstructed during hypnosis. Light waveform is the visual evoked potential while the right visual field is obstructed by positive hypnotic hallucination. Note that from 140 to 320 milliseconds after the stimulus, hypnotic obstruction and selective inattention appear to exert opposite effects on the visual evoked potential.
as the N140. This negative deflection is consistently seen as a response to selective attention to somatic stimulation (Allison 1982, Michie 1984, Naatanen and Michie 1979). Postulating that somatic conversion disorders may represent a form of selective attention, Maldonado (1997, 2001) studied a group of patients presenting with lateralized (i.e., unilateral) deficits using SERPs. If indeed these patients are constantly monitoring the affected body part or side, they should show an enhanced N140 on the affected side. This proved to be the case. Maldonado found that subjects exhibited a “normal N140” on the unaffected side (as expected in all “normal controls”), but an enhanced N140 on the affected side (Maldonado 2006). Even more remarkably, when the researchers provided suggestions for time regression (e.g., 2 weeks prior to the onset of symptoms), subjects experienced complete normalization of the SERP’s response, showing only the “classic N140” bilaterally (Figure 94–5). At the end of the trial, the SERP’s tracing returned to the previous pattern, that is, a classic N140 on the unaffected side and an enhanced N140 on the affected side. These findings suggest the possibility of an unconscious, autohypnotic model used by patients suffering from conversion disorder in order to create their symptoms.

**Brain Imaging**

Despite the relatively limited research on hypnosis using newer brain-imaging techniques, such as positron-emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI), new data are slowly emerging. PET scan studies have demonstrated a global increase in cerebral perfusion during hypnosis (Ulrich et al. 1987), while they demonstrated no change during the use of autogenic training in normal subjects. Work using PET imaging of the brain has led to the discovery that attentional processes can be subdivided into a series of components with different neuroanatomical localizations (Posner and Petersen 1990). The posterior attentional system involves orienting, with activation of the posterior or prestriate cortex. Focusing of attention is associated with activity in the anterior cingulate gyrus. Arousal involves activity in the right frontal cortex, consistent with the definition of hypnosis as a state of focal attention and heightened concentration. This suggests that during hypnosis, there is specific activation of the anterior attentional systems involving focusing (anterior cingulate) and arousal (frontal, especially on the right). Therefore, these imaging techniques may prove useful in identifying subsystems within the brain devoted to specific types of perceptual and cognitive processing in hypnosis.

In the last few years new studies shed further light into the neurophysiology of hypnotic phenomena. Rainville et al. (1997) demonstrated that hypnotic reduction of the perceived unpleasantness of a stimulus was associated with significant changes in pain-evoked activity within anterior cingulate but not somatosensory cortex in PET studies. PET scans were also used by Szechtman et al. (1998) to measure rCBF of highly hypnotizable subjects asked to produce vivid auditory hallucinations. They found that subjects capable of producing the hallucinations had increased rCBF in the right anterior cingulate gyrus. Of interest, the “externality” and “clarity” of the hallucinations were highly correlated with blood flow in this region.

Later, they investigated the effects of hypnosis and suggestions to alter pain perception on the PET-measured rCBF and the EEG measures of brain electrical activity, in highly hypnotizable subjects under different experimental conditions (Rainville et al. 1999). Pain was induced by immersion of a hand in either water at room temperature or painfully hot water. The findings suggest that hypnosis was accompanied by significant increases in both occipital rCBF and delta EEG activity, which were highly correlated with each other ($r = 0.70$, $P < 0.0001$). Peak increases in rCBF...
were also observed in the caudal part of the right anterior cingulate sulcus and bilaterally in the infero-frontal gyri. Hypnosis-related decreases in rCBF were found in the right inferior parietal lobule, the left precuneus, and the posterior cingulate gyrus. Hypnosis with suggestions produced additional widespread increases in rCBF in the frontal cortices predominantly on the left side. Moreover, the medial and lateral posterior parietal cortices showed suggestion-related increases, overlapping partly with regions of hypnosis-related decreases. Results support a state theory of hypnosis in which occipital increases in rCBF and delta activity reflect the alteration of consciousness associated with decreased arousal and possible facilitation of visual imagery. Frontal increases in rCBF associated with suggestions for altered perception might reflect the verbal mediation of the suggestions, working memory, and top-down processes involved in the reinterpretation of the perceptual experience.

Several years later, the same group of researchers replicated and extended their original findings using PET in normal volunteers (Rainville et al. 2002). Immediately after each of eight PET scans performed before (four scans) and after (four scans) the induction of hypnosis, subjects rated their perceived level of “mental relaxation” and “mental absorption.” Regression analyses between rCBF and self-ratings confirm the hypothesized involvement of the anterior cingulate cortex (ACC), the thalamus, and the pontomesencephalic brainstem in the production of hypnotic states. Hypnotic relaxation further involved an increase in occipital rCBF that is consistent with our previous interpretation that hypnotic states are characterized by a decrease in cortical arousal and a reduction in cross-modality suppression (disinhibition). In contrast, increases in mental absorption during hypnosis were associated with rCBF increases in a distributed network of cortical and subcortical structures previously described as the brain’s attentional system. These findings support the state theory of hypnosis in which the basic changes in phenomenal experience produced by hypnotic induction reflect, at least in part, the modulation of activity within brain areas critically involved in the regulation of consciousness.

Wik et al. (1999), using PET scans, studied the effect of hypnoanalgesia in patients with pain associated to fibromyalgia. When comparing the results during hypnotically induced analgesia and resting wakefulness they found that patients experienced less pain during hypnosis than at rest. At the same time the cerebral blood flow was bilaterally increased in the orbitofrontal and subcallosal cingulate cortices, the right thalamus, and the left inferior parietal cortex, and was decreased bilaterally in the cingulate cortex. They concluded that the observed blood-flow pattern supported the notion of a multifactorial nature of hypnotic analgesia, with contributions from cortical and subcortical brain regions. Hypnotic alteration of perception involves changes in primary sensory association cortex as demonstrated by Kosslyn et al. (2000). The authors performed PET scans using $^{15}$O-CO$_2$ of highly hypnotizable subjects asked to see a colored pattern in color in a number of visual stimuli, included gray and white stimulus. Under hypnosis, both the left and right hemisphere color areas were activated when they were asked to perceive color, whether they were actually shown the color or grayscale stimulus; moreover, these brain regions had decreased activation when subjects were told to see the grayscale, whether they were actually shown the color or grayscale stimulus.

Similarly, Faymonville et al. (2000) used PET scans to identify the brain areas in which hypnosis modulates cerebral responses to noxious stimuli. They compared brain images of subjects in a hypnotic resting state with mental imagery and a hypnotic state with stimulation (warm nonnoxious vs. hot noxious stimuli applied to right thanar eminence). Statistical parametric mapping demonstrated that noxious stimulation caused an increase in rCBF in the thalamic nuclei, anterior cingulate, and insular cortices. The hypnotic state induced a significant activation of a right-sided extrastriate area and the anterior cingulate cortex. The interaction analysis showed that the activity in the anterior (mid-) cingulate cortex was related to pain perception and unpleasantness differently in the hypnotic state than in control situations. Results also showed that hypnosis decreased both pain sensation and the unpleasantness of noxious stimuli and suggest that hypnotic analgesia with an instruction that the pain will not be bothersome (rather than literally reduced in intensity) is mediated by reduced activity in the ACC.

Later in 2003, his team assessed changes in cerebral functional connectivity related to the hypnotic state, compared to simple distraction and the resting state among highly hypnotizable right-handed volunteers using H2(15)OPET (Faymonville et al. 2003). The experimental conditions were hot noxious or warm non-noxious stimulation of the right hand during resting state, mental imagery, and hypnotic state. They found that hypnosis, compared to the resting state, reduced pain perception by 50%, while the pain perception during rest and mental imagery was not significantly different. Analysis of PET data showed that the hypnotic state, compared to normal alertness (i.e., rest and mental imagery), significantly enhanced the functional modulation between midcingulate cortex and a large neural network encompassing bilateral insula, pregenual ACC, pre-supplementary motor area, right prefrontal cortex and striatum, thalamus, and brainstem. These findings point to a critical role for the midcingulate cortex in the modulation of a large cortical and subcortical network underlying its influence on sensory, affective, cognitive, and behavioral aspects of nociception, in the specific context of hypnosis.

More recently, PET imaging studies have confirmed that hypnosis, when used to produce hypnotic analgesia, can modulate the cerebral network involved in noxious perception (Faymonville et al. 2006). Compared to the resting state, hypnosis reduced pain perception in somatosensory cortex by approximately 50%. The hypnosis-induced reduction of affective and sensory responses to noxious thermal stimulation were modulated by the activity in the midcingulate cortex (area 24a). Also, compared to normal alertness (i.e., rest and mental imagery), the hypnotic state significantly enhanced the functional modulation between midcingulate cortex and a large neural network involved in sensory, affective, cognitive, and behavioral aspects of nociception.

Thus, the observed changes in subjective experience achieved while in a hypnotic state are reflected by changes in brain function similar to those that occur in perception. These findings suggest that hypnotic alteration of perception is more than mere compliance with suggestion, but rather it involves alteration in sensory experience.
Enhancing Hypnotizability

A number of articles have addressed the issue of enhancement of hypnotic capacity. To date, all the published papers in this topic consist of case reports, small samples, or anecdotal cases, making it difficult to generalize the results. Efforts to enhance measured hypnotizability through behavioral training sometimes result in an increase in scores, but trait hypnotizability still accounts for three times the variance in performance (Frischholz et al. 1982a). Nevertheless, the limited data available suggest that sensory deprivation (Sanders and Giolas 1991) and certain stimulant psychomimetic drugs (Sjoberg and Hollister 1965) may enhance hypnotic responsiveness. In summary, there are no well-conducted studies proving that any particular technique, device, or substance may enhance hypnotic capacity. In fact, every study conducted so far seems to suggest that hypnotizability may not be enhanced (Page et al. 2002).

Whether high hypnotic ability enhances other forms of alternative healing or just predicts it is not clear. Nevertheless, Lu and Lu (1999) studied the combined effect of acupuncture and hypnosis. Their findings suggest that there is synergy between the two treatment modalities. In their study, hypnosis augmented the effect of acupuncture, resulting in better treatment outcomes. Similarly, hypnosis can be used to enhance the effect of other therapeutic techniques such as cognitive–behavioral therapy (Allison and Faith 1996, Bryant et al. 2005, 2006, Frischholz et al. 1982a, Kirsch et al. 1995), biofeedback (Frischholz and Tryon 1980, LaRocca et al. 1985, Tellegen 1981), acupuncture (Katz et al. 1974, Knox and Shum 1977, Loitman 2000, Lu et al. 2001, Lu and Lu 1999), relaxation techniques (Covino and Frankel 1993, Garvin et al. 2001, Iham 1962, Morrison 1988, Spira and Spiegel 1992), meditation-based techniques (Biswas et al. 2000, Brown et al. 1982, Delmonte 1990), and other behavioral techniques (Brown and Fromm 1987).

Conclusion

Hypnosis is a natural state of mind. As a trait, it can be measured and mastered. Even though it occurs naturally, not every body has the same hypnotic capacity. It involves the ability to concentrate intensely, the capacity to receive new information, and the flexibility to change behavior. The capacity to experience hypnosis constitutes a therapeutic resource in the patient that can be mobilized by formal hypnosis during the therapy session and self-hypnosis exercises afterward. Strategies such as cognitive restructuring under hypnosis can help patients alter their perspective on their symptoms by experiencing symptom resolution as an occasion to enhance their sense of mastery. Many therapeutic approaches using hypnosis involve changing the patient’s perspective on the relationship between the psychological and the physical state, dissociating mental from physical stress and suffering (i.e., pain), adopting a stance of protectionism toward the body rather than fighting destructive urges (i.e., quality of life vs. smoking), or learning to see sudden discontinuities in consciousness (i.e., flashbacks and episodes of dissociation) as understandable and controllable hypnotic phenomena.

Training patients in the use of self-hypnosis can facilitate the therapeutic process. This use of hypnosis can communicate the therapist’s desire to enhance the patient’s mastery and independence. Thus, patients can learn to use their hypnotic capacity rather than be used by it. This newly developed ability can be understood as an exercise in self-control rather than submission to the will of the therapist. It can be used to enhance control of somatic processes, reactions to anxiety-provoking stimuli, and impulsive behavior.

About the Authors

José R. Maldonado, M.D.
Associate Professor of Psychiatry and Behavioral Sciences; Chief, Medical and Forensic Psychiatry Section; Director, Medical Psychotherapy Clinic, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine; Medical Director, Consultation/Liaison Service, Stanford University Medical Center, Stanford, California.

David Spiegel, M.D.
Willson Professor and Associate Chair of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine; Medical Director, Stanford Center for Integrative Medicine, Stanford University Medical Center, Stanford, California.

Chapter 94 • Hypnosis 2025

As illustrated in the case example, a patient’s emotional and behavioral responses to illness may be as important to address as the concurrent medical condition. Challenging patient presentations are common across a wide range of medical settings—from inpatient wards to outpatient clinics, from primary care clinics and various medical specialty practices. Some patients are relentless in their presentations of unexplained symptoms. Many of these patients often demonstrate a corresponding high level of emotional and physical disability and distress that further complicate medical efforts and cloud effective treatment planning. Other patients fail to engage in their medical care appropriately despite ongoing efforts from their healthcare providers. Examples include the patient with consistently uncontrolled diabetes, the patient who continues to smoke despite rapid progression of chronic obstructive pulmonary disease, and the patient who goes through much effort to avoid necessary medical care as illustrated in Case Example 1. Healthcare providers can become perplexed by these types of patients. They often ask, “Is there a medical explanation for their patient’s reactions or is it psychogenic?” While this seems like a simple and obvious question to ask, the answer is often neither simple nor obvious. Nonetheless, the benefits of psychological interventions have been demonstrated to offset costs associated with various medical conditions. In a classic meta-analysis of 58 controlled studies and the Blue Cross/Blue Shield Federal Employee Plan, Mumford and colleagues demonstrated an 85% reduction of total healthcare utilization, primarily through a reduced inpatient stays (Mumford et al. 1984). Thus, the need to provide holistic healthcare that attends to the emotional and physical well-being of the patient is evident.

Behavioral medicine is one approach to address the overlap between health and human behavior. In this chapter, we provide a general introduction to behavioral medicine for the healthcare provider who may have a limited or extensive understanding of traditional mental health concepts and techniques. A brief summary of key historical movements and the events leading to the formal emergence of the field of behavioral medicine are reviewed to provide the reader with a solid understanding of the foundation and principles upon which behavioral medicine rests. Next, we seek to provide the reader with a sense of how the behavioral medicine specialist approaches clinical situations. We provide a brief overview of selected content areas of historical significance or novel interest within the field of behavioral

Case Example 1

A 55-year-old married real estate salesman was brought to the emergency room with a symptom similar to what he experienced 6 months earlier when he had a myocardial infarction. His symptoms began about 10:00 in the morning when, alone at his desk, he began to experience general unease and discomfort; and then during the next few minutes growing “pressure” of his mid-anterior chest and an aching sensation down the left arm to the elbow. While he initially thought that he was having a second heart attack, he dismissed this possibility in favor of “fatigue,” “gas,” “muscle strain,” and finally “emotional tension.” He alternated between sitting quietly to “let it pass,” pacing about the office to “work it off,” and taking Alka Seltzer. When he could no longer deny the probability, if not the certainty, of another heart attack, a different set of values emerged as his fear of losing control over his own destiny gained ascendancy. He was finally persuaded by a coworker to seek care. By the time he was admitted to the emergency department, he was no longer having any discomfort. Thirty minutes later, however, in the midst of a continuing and stressful workup, he abruptly lost consciousness. The monitor documented ventricular fibrillation, which was successfully corrected by defibrillation and he made an uneventful recovery.

Historical Foundations of Behavioral Medicine

Even before the emergence of behavioral medicine, there have been efforts to understand the interactions between human behavior and physiology. While a comprehensive review of previous philosophical and scientific attempts toward explaining mind–body interactions is beyond the scope of this chapter, brief reviews of the historical context and key concepts preceding the establishment of the field of behavioral medicine are important to mention.

During ancient times, Hippocrates and Galen are credited for proposing the notion of temperaments to explain the relationship between the body and mind by categorizing patterns of human behavior according to the relative distribution of four principal bodily fluids: blood, yellow bile, black bile, and phlegm (Maher and Maher 1994, Irwin 1947). For example, an excess of phlegm was associated with a phlegmatic disposition characterized by a tendency to be slow or lazy while an excess of black bile was believed to cause a melancholic or depressive disposition. The concept of dualism emerged during the Renaissance period, primarily through the philosophical works of Rene Descartes. In his original conceptualization of dualism, Descartes posited not only the separation between the mind and body, but also suggested that the pineal gland was the site of mind–body interactions. Dualism further suggested a division of labor among healers: Physicians and other traditional healthcare specialists were expected to practice within the domain of the body, which was metaphorically presumed to be a “machine.” In contrast, philosophers and theologians would address concerns of the “soul,” which was presumed to continue beyond the death of the body and was readily incorporated into existing Judeo-Christian notions of spirituality. In the 19th century, Franz Gall proposed the “science” of phrenology based on the following beliefs: (1) the mind is located in the brain; (2) there is localization of intelligence and personality factors within the brain; and (3) well-developed intellectual and personality factors would correlate with an increase in size of the corresponding part of the brain and interpreted by impressions of the skull (Hilgard 1987).

These three earlier approaches—Hippocrates’ temperaments, Descartes’ dualism, and Gall’s phrenology—are a few examples of prior efforts to understand the mind–body connection before the emergence of behavioral medicine. All three approaches live on in many of our theories and formulations that we consider “modern.” For example, Switakowsky (2000) posits that dualism has contributed to the pervasive mechanistic and reductionistic models commonly seen in medical practices by which the locus of intervention focuses on the body to the exclusion of the “lived experience” of the whole person.

Subsequently, psychoanalytic theory has also addressed the mind–body issue. In fact, psychoanalysis came to its beginnings through a consideration of physical or somatic symptoms. Sigmund Freud and Joseph Breuer, in their Studies of Hysteria (Breuer and Freud 1895/1955), formulated a specific theory of mental functioning to explain the inexplicable symptoms of patients diagnosed as hysterical. The idea that symptoms of bodily dysfunction could be related to the mental phenomenon of suppressed and conflicted wishes may have grown out of the work of Mesmer and other 19th century French and German physicians, but when it was put forward by Freud and Breuer it was instantly controversial. Nonetheless, Freud’s theories quickly gained popularity. His notion was that somatic involvement occurs in hysteria when psychic energy is repressed and therefore dammed up and becomes discharged by excitations through somatic realms. Freud also pointed out that the symptoms have symbolic meaning. This work was taken to extremes by some of his followers who applied it to various medical conditions—including Ferenczi, Dunbar, Borsch, Greenacre—all of whom developed various aspects of the relationship between psychoanalytic ideas and physical diseases. Franz Alexander’s work was influential in his time. He put forward the concept of specificity, alleging that the route of influence of the emotions, especially those based on mental conflict (and defense against the conscious realization of these conflicts) between unconscious wishes and the conflicting imperatives that opposed them, was through the autonomic nervous system. He had a specific psychodynamic formulation for particular illnesses. Other psychoanalytic thinkers followed. Alexander Wolff in the 1940s attempted to relate illness to life stress. Karen Horney and others emphasized the role of culture in the development of psychosomatic illness. However, these theories slowly lost ground to increasing knowledge of specific biological mechanisms of illness. The concepts such as unconscious conflict, repression, and temperament were no match for the specificity and experimental rigor of later biologically based knowledge in understanding and treating medical illnesses. For instance, the specific formulation of the role of oral fixation in duodenal ulcer disease ultimately fell to the explication of the role of the helicobacter pylori bacteria. Likewise, other illnesses yielded to biological mechanisms, though the role of emotions in the form of nonspecific influences of stress through corticosteroids and the pituitary–adrenal axis as well as the link between the psychological and immune systems are still present. As these theories of causality based on intrapsychic organization waned in influence, new directions emerged.

In the early part of the century, the need for behavioral approaches to health and disease resurfaced. One variation of this movement contributed to the parallel development of the related fields of consultation and liaison (CL) psychiatry and psychosomatic medicine. CL psychiatry began when certain hospitals explored the usefulness of psychiatrist consultants for their medical and surgical patients. The Massachusetts General Hospital, Henry Ford Hospital, Detroit, the University of Rochester, the University of Colorado, Mount Sinai Hospital in New York, and other institutions served particular roles as pioneers (Gitlin et al. 2004). In
the 1930s, the Rockefeller Foundation under the leadership of Alan Gregg funded the start of psychiatric divisions in medical hospitals, and continued to fund the development of CL psychiatry services into the 1950s. By the 1960s most academic medical centers had CL programs. Support from the National Institutes of Health under the leadership of James Eaton was also a key impetus in the 1970s and 1980s. The Academy of Psychosomatic Medicine became the chief professional group for the field. In 1987 training requirements in CL were instituted for psychiatry residency programs in the United States. Today, all residency programs must include at least 2 months of training in CL psychiatry. In 2002, CL psychiatry was recognized by the American Board of Medical Specialties as a subspecialty of psychiatry albeit under the controversial term psychosomatic medicine (Gitlin et al. 2004).

Even though CL and psychosomatic medicine are closely related to behavioral medicine, the three disciplines are not identical and have evolved from different yet converging movements. All three disciplines recognize the critical interplay of psychological, social, and physiological factors and often share similar clinical approaches. However, CL also includes areas of medical and physiological function less related to behavior per se—including medical effects of psychiatric conditions and medications. Compared to behavioral medicine practitioners, CL psychiatrists and psychosomatic medicine specialists work in acute situations with patients who are already ill and often admitted to the hospital. Consequently, most medically ill patients do not receive continuing care from specialists in CL. In contrast, outpatient services and ongoing follow up are more characteristic of behavioral medicine specialists. The following section will provide further details on the origins of the field of behavioral medicine.

The Beginning of Behavioral Medicine

The term “behavioral medicine” was likely first coined to describe biofeedback and its use for the treatment of medical conditions such as asthma and headaches (Birk 1973). However, this narrow definition was quickly supplanted by definitions of a field characterized by explicit emphasis on the integration of science of behavior with a focus on behavioral interventions in the context of health and illness. An important distinction with the existing field of psychosomatic medicine was also made that emphasized the behavioral science, as opposed to the biomedical science, roots of behavioral medicine, and this distinction almost certainly served a key role in defining and advancing this new enterprise (Gentry 1984).

Given our affiliations with Yale University, we have been particularly sensitive to the legacy that our predecessors have had in the field of behavioral medicine. For example, the efforts from two pioneering researchers—Gary E. Schwartz and Stephen M. Weiss—spearheaded the genesis of the field of behavioral medicine through their efforts to bring together a collaborative group of researchers at what would later be known as the Yale Conference on Behavioral Medicine. The impetus for their efforts drew from two distinct, yet interrelated, trends. First, scientists as well as the public at large were developing an interest in the interactions between behavior and health. However, there was no formal mechanism to evaluate and ultimately fund research that addressed these mind–body interactions. Second, the emerging interest in health and behavior interactions had not yet crystallized into a cohesive area of specialization with a foundation in theory and research as well as the development of clinical applications. It was their hope that by providing structure and definition to the evolving interest in health and behavior, a formal interdisciplinary field could be established and recognized by the public, researchers, and funding agencies (Schwartz and Weiss 1978a).

During the Yale Conference on Behavioral Medicine (Schwartz and Weiss 1978a) held in early February of 1977, the diverse group of behavioral and biomedical scientists met with the intentions of defining “behavioral medicine” and identifying goals and recommendations that would guide the development of this new field. This group initially defined “behavioral medicine” with the explicit emphasis on the importance of addressing health and illness within an integrated interdisciplinary and scientific framework as well as the recognition that contributions to specific “subareas”—such as behavioral interventions to improve health—would likely develop and should be included within the larger field of behavioral medicine. Topics related exclusively to areas of traditional behavioral research and thereby lacking any clear link with physical health—such as mental illness, substance abuse, mental retardation, and social welfare problems—were explicitly excluded from the original definition of behavioral medicine. Attendees also actively sought to distinguish behavioral medicine from psychosomatic medicine. Psychosomatic medicine was seen as a field dedicated to identifying behavioral factors that indirectly mediate biomedical endpoints. In contrast, behavioral medicine established behavioral factors as also being able to directly interact with physiology to contribute to health and illness. The emphasis on the integration and synthesis of the mind and body were clearly evident in the discussions of the forefathers of the newly evolving interdisciplinary field. To further highlight the unique aspirations of the field of behavioral medicine, the attendees also proposed to create a new peer-reviewed journal and new professional society to meet its objectives.

In a second meeting of many of the original Yale conference attendees and others at the Institute of Medicine, National Academy of Sciences, the following year, the interdisciplinary nature of the field was further emphasized and an amended definition for the field of behavioral medicine was adopted. The ramifications of increased emphasis on integration of behavioral and biomedical factors had profound influences. In essence, the field of behavioral medicine...
sought to extend beyond the issue of mind–body dualism and instead view all phenomena as cohesive integrations of biomedical and behavioral elements that could not be separated. In essence, efforts to describe health or illness as resulting exclusively from biological (or conversely, psychosocial) factors would be rejected. Moreover, this same conceptualization stood in sharp contrast to earlier efforts to exclude traditional psychiatric illnesses from the domain of behavioral medicine. With the advent of preliminary data suggesting possible underlying neurobiological contributors to mental illness, it was recognized that psychiatric disorders also likely arose from an inherent synthesis of contributing biological and psychosocial factors. Hence, the increased focus on integration of traditional mind–body issues precluded the need to limit the field of behavioral medicine to the study of diseases traditionally conceptualized as physical (vs. psychiatric) disorders (Schwartz and Weiss 1978).

In quick succession following this second meeting, significant developments secured the future of the field. In 1978, the *Journal of Behavioral Medicine* was first published, a permanent National Institutes of Health Study Section on Behavioral Medicine was created, and behavioral medicine branches of the National Heart Lung and Blood Institute and the National Cancer Institute were quickly established (Schwartz and Weiss 1978). In that same year, the *Society of Behavioral Medicine* was organized as a “multidisciplinary organization of clinicians, educators, and scientists dedicated to promoting the study of interactions of behavior with biology and the environment to improve the health and well-being of individuals, families, communities, and populations” (The Society of Behavioral Medicine; www.sbm.org). By 1984, numerous edited and single authored volumes were published that further served to define the field’s scientific and scholarly roots, its scope, and an agenda for future research, education, clinical application, and policy (Gentry 1984, Ferguson and Taylor 1980a, 1980b, Ferguson and Taylor 1981, Turk et al. 1983).

Thirty years following the Yale Conference on Behavioral Medicine, the field of behavioral medicine is clearly alive and well. The strength of the field can be judged through a consideration of its impact on life in the Western societies. For instance, it is now almost universally accepted that behavior plays key roles in the development and perpetuation of disease and illness, and that changes in behavior can promote health and well-being, reduce risk for the development of disease, promote recovery from acute illness, and enhance adjustment and adaptation to persistent health problems. Significant advances in several health-relevant domains across the entire lifespan have been informed by explicit attention to behavioral factors. There is strong evidence that behavioral interventions can improve health outcomes across several domains including, but not limited to, preventing disease onset (Kalichman 1998), decreasing pregnancy complications (Walker et al. 2002), and enhancing the immune responses (Kiecolt-Glaser et al. 2002).

Finally, a few additional developments serve to highlight more recent advances of the field. On July 1, 1995, the Office of Behavioral and Social Sciences Research (OBSSR) was established within the NIH to further institutionalize an emphasis on research at the interface of behavioral and social sciences and health-relevant concerns and to provide oversight for this focus. Additional premiere scientific journals that publish behavioral medicine research have appeared over the past three decades, including the *Annals of Behavioral Medicine*, the official journal of the Society of Behavioral Medicine. Not surprisingly, the field now has a strong international scope as manifest by the International Society of Behavioral Medicine and the *International Journal of Behavioral Medicine*. In the last several years, the American Psychological Association has recognized clinical health psychology, a discipline-specific enterprise closely linked to the field of behavioral medicine, as a specialty within the professional practice of psychology. Finally, the recent adoption by the American Medical Association of new Health and Behavior Assessment and Intervention Current Procedural Terminology (CPT) codes has been identified as an important advance that permits billing for behavioral medicine services that are linked with medical, rather than psychiatric, diagnoses, in a manner that is entirely consistent with some of the key principles and definitions of the field.

**Theoretical Foundations within Behavioral Medicine**

Behavioral medicine emerged from empirical evidence linking behavior and health that began to expand rapidly in the 1970s. Several overlapping theoretical perspectives served primary roles in informing the bulk of the research as well as the practice of behavioral medicine. Many of these theories—either in their original version or a revised re-formulation—continue to guide research and practice within behavioral medicine.

Proponents of behaviorism (Brady 1981) and cognitive social learning theory (Bandura 1977) cited the experimental analysis of behavior and a growing body of research on the efficacy of behavior therapy and behavior modification targeting the evaluation, prevention, management, and treatment of disease and physiological dysfunction. As the field continued to emerge, proponents of a cognitive–behavioral perspective articulated and emphasized a primary role of cognition, particularly appraisals, as determinants of the ways that individuals—primarily patients and/or their significant others—define health, illness, and disease. For example, cognition has an influential role in determining if a person decides to engage in health-promoting behaviors, how a person might respond to symptoms and incapacities associated with illness and subsequently engage the assistance of the healthcare system and/or community, as well as directly influencing illness and disease (Turk et al. 1983). Ultimately, the utility of these models continues to inform scientific inquiry, including the articulation of testable, meaningful hypotheses about causal and explanatory links between behavior and health and/or illness. These models have also contributed to the rapid and continued growth of the field.

**Systems perspectives**, particularly the biopsychosocial model, also had an influential role (Engel 1980, Engel 1977). The biopsychosocial perspective, advocated persistently and eloquently by George Engel, drew attention to the inextricable and reciprocal links between health and illness, behavior, and social context. This perspective highlighted the importance of inquiry at multiple levels of the organism (e.g., molecular, organ, person, family). Additional key principles of the model include the ideas that components
of the system are hierarchically arranged, that each component has multiple subcomponents and that each component is part of a larger whole, and that change or intervention at one level of the system necessarily results in changes in other levels. Systems theory stands in direct contrast to traditional medical models of disease that are largely viewed as reductionistic and stuck in mind–body dualism. And many of the implications of systems theory are difficult to implement in the present healthcare system of research, education, and patient care. The model encourages a comprehensive consideration of multiple levels of analysis when conducting a clinical assessment and when designing a treatment plan. The relationship between healthcare providers, patients, and families is also emphasized by the model. In fact, Engel suggested that the failure to appreciate the importance of the interaction between providers and patients is a critical flaw of the medical model and the practice of medicine. Similarly, the field of shared medical decision making has emerged as another area of specialization that explicitly examines the nature of patient–provider interactions (Charles et al. 2003). The complexity of the biopsychosocial model, however, also represented a challenge to scientists and clinicians who appreciated the limits of control and establishment of causation in the laboratory and healthcare setting. As Schwartz (1979, p 552) noted,

One frustrating aspect of general systems theory is that it not only teaches us how much we do not know but also points out how many things we should know in order to do justice to the specific problems under investigation.

Struggles to balance a commitment to a scientific basis of behavioral (or behavior in clinical) medicine and the complexities represented in systems perspectives such as the biopsychosocial model continue to be a source of consternation for many in the field.

Schwartz (1977) articulation of a psychobiological model of self-regulation (and disregulation), with its roots firmly in systems theory, served influential roles in advancing both the science and practice of behavioral medicine. Schwartz’s model highlighted five core components of self-regulation: (1) environmental demands; (2) central nervous system information processing; (3) peripheral organs; (4) (internal) negative feedback; and (5) (external) biofeedback (See Table 95–1). Schwartz emphasized the central role of the brain as a “healthcare system” designed to promote automatic self-regulation in the face of environmental challenges. Consistent with other systems perspectives, Schwartz further suggested that disregulation could occur at any level of the system, and that the design of interventions to promote self-regulation necessarily affect all stages or components of the regulatory system. This model of self-regulation and disregulation has served an important heuristic purpose of contributing to advances in research on biofeedback and its application in clinical settings. However, the broader influence of such thinking on investigations of self-regulatory processes and the interface between behavioral and biological systems cannot be overstated. The emergence of the field of psychoneuroimmunology is a further important outgrowth of self-regulation theory. The pioneering work of Janice Kiecolt-Glaser and others provides answers to questions such as how the experience of social stress can alter neuroimmunologic systems regulation and contribute to the common cold, influence wound healing, and influence recovery from acute illness (Kiecolt-Glaser et al. 2002).

The “cognitive revolution” in American Psychology in the 1970s and 1980s also had an impressive influence on the emerging field of behavioral medicine, and this influence persists. In 1983, Turk and his colleagues published a seminal volume articulating a cognitive–behavioral perspective on behavioral medicine and health and illness issues. The example of pain management was employed to emphasize the central role of cognition in determining adjustment, adaptation, and recovery from acute and chronic illness. Turk (2002) articulated five key assumptions that characterize the cognitive–behavioral perspective on treatment of illness and other health-related problems, although these assertions have certainly had much broader influences on behavioral medicine research and practice.

The concept of stress looms large in both the biological and social sciences. Although the concept has been around for several centuries, only in the past 60 years or so has it been operationalized to the extent that it has served heuristic ends in terms of systematic investigation, particularly in the health arena. In the behavioral medicine field, no theoretical discussion of stress has a greater impact than the stress, appraisal, and coping model of Lazarus and his colleagues (Lazarus and Folkman 1984). In contrast to the historical roots of the concept of stress that have characterized it as either an environmental stimulus or an organism’s response, Lazarus emphasizes the relationship between the person and the environment. This international model takes into account individual differences in persons’ biological, emotional, and behavioral responses to similar environmental events. The model proposes that psychological stress is a function of a person’s cognitive appraisal of an interaction with the environment that taxes or exceeds the person’s resources and endangering his or her well-being. Also central to the model is the concept of coping that Lazarus and Folkman define as “constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are

appraised as taxing or exceeding the resources of the system” (p 141). This comprehensive model has its historical roots in a broad array of theoretical perspectives and empirical evidence. It continues to be refined and asserts influence on the field of behavioral medicine from basic studies of mechanisms underlying the development of disease to public health campaigns informed by population-based studies of health risk behavior modification and health promotion.

The transtheoretical model (TTM) of behavior change (Prochaska and DiClemente 1984) has been offered as an integrative theoretical model that may help to explain differences in persons’ success during treatment for a range of psychological and physical health problems. The model was developed as a result of a comparative analysis of influential theories of behavior change that culminated in a “systematic integration” of theories. This comparative research identified 10 distinct processes of change that individuals used at different times (stages) in their behavior change (e.g., developing conscious awareness of unconscious dynamics from Freudian theory, contingency management from Skinnerian theory, and helping relationships from Rogerian theory).

The TTM was based on cognitive concepts such as emotions, feelings, beliefs, and attitudes and provided an alternative to a number of established theoretical frameworks including those articulated above. The core constructs of the TTM are the processes of change, decisional balance, self-efficacy, and temptation. Each construct represents an important dimension in terms of explaining how and why individuals make health-related behavioral changes. This model posits that individuals go through specific “stages of change” when attempting to modify a certain behavior and that they vary in terms of their “readiness” or how prepared they are to make a behavioral change. The stages are typically described as precontemplation (no intention of behavioral change in the near future), contemplation (thinking about the possibility of behavioral change at some point in the future but have yet to commit to taking action), preparation (actively considering making changes in their behavior within the next month), action (active work toward desired behavioral change including modification of environment, experiences, or behavior), and maintenance (ongoing, active work to maintain changes made and relapse prevention).

Research has suggested that persons who successfully change their behavior may use different behavior change strategies or processes of change to progress from one stage to the next (e.g., increasing insight into unconscious intrapsychic dynamics, catharsis, and counterconditioning)—an observation that has implications for tailoring interventions to specifically target persons in a specific stage to promote or motivate “forward stage movement.” Not surprisingly, this model has been influential in encouraging the investigation of its validity and utility in promoting health-relevant behavior change such as tobacco use cessation, promotion of exercise, weight management, improved lipid control, cancer screening, and self-management of pain, and other health concerns.

Upon review of key theories within the field of behavioral medicine, several patterns emerge. First, these theories are empirically based. Experimentation in both clinical and laboratory settings have contributed to subsequent development of clinical applications within behavioral medicine. Second, the endorsement of a biopsychosocial perspective within behavioral medicine remains a prominent, central focus. Behavioral medicine clearly favors integration and synthesis over reductionism; hence, it stands in sharp contrast to the concepts and implications of dualism, as well as other monocausal theories of health and illness. Third and less evident than the themes noted before in the second set of patterns is the broad developmental context through which behavioral medicine seeks to understand health behaviors. Indeed, a firm understanding of proximal as well as distal causes of health and health-related behaviors is required to formulate the prototypical biopsychosocial conceptualization that defines behavioral medicine. Hence, behavior medicine focuses on health-related concerns across the lifespan with theories and applications to address health promotion and disease prevention as well as adjustment and coping to acute and chronic illness.

Selected Health Issues within Behavioral Medicine

This section will provide a representative rather than an exhaustive review of selected topics within behavioral medicine. We have organized these topics into preventive measures and treatment of specific diseases and symptom complexes, multidisciplinary approaches to delivery of services, and special topics. In many respects, the field of behavioral medicine can be conceptualized as a large interdisciplinary umbrella that attempts to integrate biological, behavioral, and psychosocial factors in an effort to understand health and illness. Within this large umbrella, there are multiple lines of inquiry that have advanced the comprehension of the etiology, maintenance, and/or treatment of a variety of health-related problems. Examples include nicotine...
use, chronic pain, insomnia, and palliative care as well as a wide array of specific disease states. There are also areas of study that explore broader issues faced within the healthcare environment that range from interpersonal factors (e.g., the doctor–patient relationship) to population-based concerns (e.g., health disparities). In this section, we present a brief overview of the various research and clinical applications within the field of behavioral medicine.

Prevention and Approaches to Lifestyle Modification

Smoking and Tobacco Use

An expansive body of research has established a strong link between nicotine use (including cigarette smoking) and multiple physical disorders including heart diseases, lung diseases, and several forms of cancer (Brantley and Garrett 1993, Russell and Eptein 1988), not to mention the deleterious effects on the unborn fetuses of pregnant smokers (Kleinman et al. 1988). Furthermore, recently emerging literature highlights the harmful effects of second-hand smoke (Stayner et al. 2007). According to epidemiological research, 20.8% of Americans are current smokers (Health, United States 2006) with the highest risk for nicotine dependence occurring in the first 16 years after daily smoking began (Breslau et al. 2001). The Centers for Disease Control (CDC) currently ranks nicotine use as the leading cause of preventable death in the United States, with approximately 440,000 deaths per year attributed to nicotine use (CDC CDCaP 2000). The annual financial burden due to cigarette purchases alone for the average smoker is estimated to be $1,000 per year (Group VPSSH 2005). Despite the landmark Surgeon General’s Report of 1964 (US Department of Health, Education, and Welfare 1964) that conclusively documented the pervasive health risks associated with tobacco use, it remains a formidable public health concern associated with staggering financial costs across the globe—especially in areas where there is little advocacy for antismoking efforts.

Consequently, efforts to reduce nicotine use have the extraordinary possibility of not only being salubrious, but also cost-effective. Mass media campaigns including community and school-based interventions have demonstrated modest success (Flynn et al. 1994, Geller and Costanza 1992), although the efficacy of these programs at educating minority and underserved populations has been questioned (Pierce et al. 1989). Within the United States, legislative action warning label mandates on tobacco products (Federal Cigarette Labeling and Advertising Act Vol 15 U.S.C. 1965) and bans on radio and television cigarette advertising have been credited with the gradual decline in the prevalence of US cigarette smokers since the 1950s (Myers et al. 1981).

With medical settings, there are three broad approaches for promoting tobacco cessation: (1) the use of a nicotine replacement therapy (NRT), such as the nicotine patch, gum, or lozenge; (2) the use of prescription medications specifically for smoking cessation (such as bupropion SR); and (3) behavioral interventions (Law and Tang 1995). While all three of these broad modalities of treatment as well as provider-delivered behavioral interventions as brief as 3 minutes have been found to be effective, higher smoking cessation quit rates are associated with the more intensive treatments that include continued counseling either delivered alone or in combination with a nicotine replacement aid (Fiore et al. 2000, Fiore and Schroeder 2003). As a result, a team approach—including primary care providers as well as multiple modes of intervention including written materials, videos, telephone calls, and brief telephone and face-to-face contact with other allied healthcare professionals, in addition to standard nicotine replacement and/or prescription medications—has been advocated to address nicotine dependence (Lichtenstein et al. 1996).

Obesity and Sedentary Behavior

Obesity is an obvious public health concern. There has been a noteworthy increase in the prevalence of obesity since the 1980s with approximately 67% of Americans between the ages of 20 and 74 being classified as overweight or obese by 2003–2004 national surveys (Gibson et al. 2006). Obesity is also associated with the increased mortality and morbidity of a variety of conditions such as hypertension, hypercholesterolemia, diabetes, coronary artery disease, congestive heart failure, stroke, gallbladder disease, osteoarthritis, sleep apnea, back pain, and certain types of cancer (Mokdad et al. 2001, Must et al. 1999). Children and adolescents who are overweight or obese are also at increased risk for hypercholesterolemia, liver problems, diabetes, as well as continued obesity throughout adulthood (Dietz 1998).

The cost of obesity due to increased healthcare utilization, and loss of productivity and/or wages earned, is estimated to be over 110 billion annually in the United States alone (Thomas 1995). Moreover, there is an emerging body of research that highlights the pervasive negative effects of social stigma and discrimination that is commonly experienced by individuals who are obese and that also contributes to reduced employment and inferior medical care (Puhl et al. 2005, Puhl and Brownell 2003, Crandall 1994, Kutcher and Bragger 2004, Pingitore et al. 1994).

Scholars and policy makers are engaged in an ongoing debate on how to address most effectively the current global obesity epidemic. An ever-growing variety of medical and commercial diet programs for weight reduction clamor for adherents with current trends focusing on overall calorie restriction, regulation of glycemic load, and targeted reduction of fats, carbohydrates, and/or sugars—either as a sole approach toward weight loss or in combination. Though each diet boasts positive results, a recent randomized clinical trial demonstrated overall modest weight reduction and decreases in health risks and little difference among highly popularized dieting approaches (Dansinger et al. 2005). Other approaches include behavioral interventions (Brownell 2004), surgical approaches including the recently popularized gastric bypass approach and the lapband procedure (Shinogle et al. 2005), as well as public policy and legislation changes aimed at restricting public access to high caloric products (Brownell and Horgen 2003).

Specific Disease and Symptom Complexes

In this section, we discuss representative approaches to specific diseases and symptom complexes. Many of the illnesses and symptom complexes that we have chosen are chronic illnesses, and before discussing them specifically, it may be well to review briefly some of the ideas that have been put forward
about managing and caring for chronically ill patients. Wagner et al. (1996) have been substantial leaders in proposing an organized approach to those with chronic illness. Their view of the optimal approach to healthcare improvement entails six elements: (1) patient self-management support; (2) decision support to use the highest standards of evidence-based medicine; (3) clinical information systems to provide clinicians with useful data at each encounter; (4) delivery system design of a multidisciplinary team that is well disciplined in the conduct of the different roles and which communicates well; (5) use of community resources; and (6) positive interactions with the healthcare system.

In addition, the managed care industry has created an approach to chronic disease management, disease management, which is estimated to be a $1.1 billion segment of American healthcare (Web site MCM; http://www.managedcaremag.com/archives/0509/0509.qna_lewis.html). Disease management is a coordinated system of healthcare interventions and communications with both practitioners and patients, designed to educate and urge/require that prevention and evidence-based practice guidelines be followed. It is used heavily in illness in which patient discretionary behavior is believed to be important such as diabetes, chronic obstructive pulmonary disease, ischemic heart disease and heart failure, as well as asthma. The Disease Management Association of America (DMAA) has defined six essential elements of disease management: (1) population identification and orientation; (2) evidence-based practice guidelines; (3) collaborative practice models; (4) patient self-management education; (5) process and outcome evaluation and management; and (6) routine feedback reporting (Web site D; http://www.dmaa.org/dm_definition.asp). Generally, these approaches are carried out by industry and the claimed results of return on investment are not always available to be evaluated by disinterested third parties.

Somatoform Disorders and other Unexplained Medical Symptoms

Somatoform (i.e., having the form of physical illness) disorders are marked by persistent symptoms or concerns that cannot be accounted for by diagnosable medical conditions. They are grouped together by their presentation, rather than by etiology or pathophysiology. Somatoform disorders should be distinguished from factitious disorder, which is the conscious feigning or induction of illness for the secondary gain of the sick role, or malingering, which is the conscious production of illness for objective gain. As defined by the DSM-IV-TR (Association 2000), the somatoform disorders include hypochondriasis, the continuing presence of anxiety regarding the presence of medical illness beyond any reasonable medical basis. Somatization disorder is distinguished by multiple unexplained medical symptoms in a range of organ systems, beginning before age 30 and persisting over years. Conversion disorder is the presence of sensory or motor symptoms not related to a medical condition and thought related to psychological factors, while pain disorder is similarly defined with regard to pain not due to or disproportionate to illness. Body dysmorphic disorder is unreasonable preoccupation with a defect in appearance, either imagined or beyond that objectively present. Undifferentiated somatoform disorder is the diagnosis applied to patients with unexplained symptoms persisting over more than 6 months, and all other patients with “somatoform” symptoms are lumped together as somatoform disorder NOS. The largest fraction of patients with a somatoform disorder certainly are those who fall into the undifferentiated or NOS groups (Janca et al. 2006, Barsky et al. 2005): for example, in a recent study in a general practice population 13% of patients were found to have undifferentiated somatoform disorder and 3% were found to have other somatoform disorders (de Waal et al. 2004).

Unexplained medical symptoms represent a substantial clinical problem. About 25–50% of primary care medical visits concern symptoms that lack medical explanation (Barsky et al. 2005). About 13% of patients in primary care clinics present with recurrent or persisting unexplained symptoms, meeting criteria for undifferentiated somatoform disorder (de Waal et al. 2004). Somatizing patients use approximately twice the outpatient and inpatient care that nonsomatizing patients do, even controlling for psychiatric and medical conditions (Barsky et al. 2005). Somatizing patients often generate considerable frustration in their physicians, who lack the expertise or the time to deal with the patient’s unrelenting complaints.

From the behavioral medicine viewpoint, the most exciting development of the last 15 years has been the demonstration that cognitive–behavioral therapy (CBT), in individual therapy with a trained practitioner, is effective in somatoform disorders. With hypochondriasis, two randomized controlled trials of CBT, addressing illness beliefs and illness-related behaviors, have demonstrated therapeutic effects (Clark et al. 1998, Warwick et al. 1996). A recent NIMH-funded trial in 187 subjects also found modest but significant improvement (treatment effect size 0.31 at 6-month follow up), with a 6-visit intervention that was scripted in detail (Barsky et al. 2005). Therapeutic studies in conversion disorder in general are numerous but have been limited to case reports and case series, and with few true randomized controlled studies (Ruddy and House 2005). With regard to nonepileptic seizures (“pseudoseizures”), there is one open label trial of CBT that demonstrated notable effect on seizure frequency, with mean seizure frequency decreased approximately sixfold and with 13 of 16 completing subjects having at least a 50% decrease in seizure frequency (Goldstein et al. 2004). Somatization disorder was found to have some response to CBT group interventions in controlled trials (Lidbeck 1997, Kasner et al. 1995). A recent government-funded, well-manualized randomized controlled trial in 84 subjects found a 10-visit CBT intervention more effective than a control intervention, with 40% of subjects with the CBT intervention rated as at “much improved” or better, compared to 5% with the control intervention at 15-month follow up (Allen et al. 2006). With regard to the patient with multiple medically unexplained symptoms or undifferentiated somatoform disorder, several randomized controlled trials have demonstrated the benefit of CBT (Sumathipala et al. 2000, Smith et al. 2005) as well as in several disorders that are at least in part functional, such as irritable bowel syndrome or fibromyalgia (Kroenke and Swindle 2000). It should be noted that many studies have examined methods for improving the ability of primary care providers to interact with and treat somatizing patients, but such research has also highlighted the difficulty...
of teaching CBT approaches to practitioners and the usefulness of consultants with expertise in behavioral approaches in medicine (King et al. 2002).

In this chapter, we have emphasized the need for an integrated, biopsychosocial approach in behavioral medicine. Nowhere is this better illustrated than in the somatoform disorders. Somaticizing patients often have difficult personal, social, and familial circumstances, and may have other disorders, both psychiatric and medical, complicating their care. The behavioral medicine consultant may apply therapies directed toward a somatizing illness specifically, but likely will need to take a broader view of the patient and his environment as well. In somatoform illness, a guiding principle should be to treat the whole patient first. The somatoform disorders are an exciting area of rapid development in behavioral medicine.

HIV and AIDS

AIDS is a devastating medical event and the co-occurrence of psychiatric illness can predominate throughout the course of the illness and have a major impact on the patient’s ability to adhere to the regimented, highly active antiretroviral therapy (HAART) and other aspects of medical care (Starace et al. 2002, Wagner et al. 2003). Furthermore, the course of illness can be complicated by not only the vicissitudes of the biological illness but also by the extremely stressful, co-occurring life events, thereby further complicating efforts to distinguish between AIDS/HIV symptoms that may mimic psychiatric conditions, psychosocial factors contributing to emotional stress, and combinations thereof. These include unusual infections, such as toxoplasmosis, cryptococcal meningitis, syphilis, as well as medication effects of interferon, antibiotics, antihypertensive agents, steroids, and other symptoms such as abdominal distress, chronic pain, and signs of central nervous system activation.

Nonetheless, psychiatric conditions are common among individuals suffering from HIV/AIDS and are often under-diagnosed (Asch et al. 2003). Prevalence rates of depression within the patient population range between 4 and 45%, with most estimates hovering around 36% (Basu et al. 2005). Similarly, rates of anxiety disorders can be as high as 38% among individuals with HIV/AIDS (Bing et al. 2001, Elliott 1998). Cognitive disorders including AIDS dementia complex (ADC) (Price 2002) and substance abuse can also be present. Mental illness among individuals with HIV/AIDS can be especially problematic. In order to provide the highest quality of care, the practitioners must not only address exacerbation of depression and dementia but also high risk behaviors including unsafe sex practices as well as suicidal and homicidal risks among individuals with co-occurring HIV/AIDS and psychiatric conditions (Haller and Miles 2003, Doudaithy et al. 2003).

A major challenge among individuals with HIV/AIDS is the “pill burden” phenomenon associated with having a complex oral medication regime (Basu et al. 2005). Thus, special effort should be made to simplify treatment regimes and avoid unnecessary polypharmacy. Recommended psychopharmacological approaches are available for managing symptoms of depression and anxiety among individuals with AIDS/HIV that take into account not only the potential for substance use but also medication interactions with HAART (Fernandez and Levy 1991, Tonks 2003). In addition, CBT, interpersonal psychotherapy (IPT), and physical exercise have been found to be effective for managing psychiatric symptoms that often co-occur with HIV/AIDS (Full et al. 2004, Ciccolo et al. 2004).

Chronic Pain

Perhaps no other area of behavioral medicine has had a greater influence on practice and policy than the field of pain management. Accepted definitions of pain highlight the multidimensional nature of pain and emphasize interactions between biological and psychological systems (Flor et al. 1990, Melzack and Wall 1982, Turk and Okifuji 2002). According to the International Association for the Study of Pain, pain is “[a]n unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage” (Merskey 1979). It is accepted as a complex perceptual experience involving all domains of persons’ lives, and multidimensional and multidisciplinary approaches to pain assessment and management that attend to concomitant changes in physical and emotional functioning and overall quality of life, in addition to pain, per se, are essential components of optimal pain care (Smith et al. 2005, Dworkin and Biethart 2004, Gatchel and Turk 2002, Turk and Gatchel 2002).

A large, broad, and growing empirical literature continues to inform sophisticated understanding of key psychological and behavioral factors that reliably influence the perpetuation, if not the development, of pain and pain-related disability. Early work focused on personality factors—such as having a predisposition toward denying emotional and/or interpersonal distress, being overly preoccupied with somatic symptoms, or displaying features associated with a “depression-prone” personality such as pessimism—that were hypothesized to be associated with pain severity and the persistence of pain over time (Smith et al. 2005, Blumen and Heilbronn 1982, Gentry et al. 1974). Laboratory and clinical studies on relationships between pain and affect continues to be a primary focus of investigation (Fernandez and Kerns, in press). Operant behavioral theory (Fordyce 1976) has been influential in emphasizing the role of social learning in the experience of pain. Specifically, the model has played an important heuristic role in informing research that has identified the role of social contingencies (e.g., expressions of sympathy from family members and friends, disability payments, prescription medications) for overt expressions of pain, termed “pain behaviors” including verbal complaints of pain and nonverbal expressions of pain (e.g., sighing, moaning), visits to doctors, avoidance of work-related activities and social responsibilities (Leonard et al. 2006, Romano et al. 1995, Weiss and Kerns 1995). Turk’s cognitive–behavioral perspective (Turk et al. 1983) played an important role in encouraging research that led to the identification of cognitive factors strongly and reliably positively associated with pain severity and disability. Among factors that have the strongest empirical support are such constructs as pain catastrophizing (Turner and Aaron 2001), fear avoidance (Vlaeyen and Linton 2000), low self-efficacy and lack of perceived control (Arnestein et al. 1999, Litt 1988), and passive pain coping (McCracken and Eccleston 2003).

Significant advances have continued on the clinical assessment and management front as well, including the
proliferation of an extensive array of psychometrically sound assessment strategies including semi-structured interviews, questionnaires, and inventories, diaries, behavioral observation methods, psychophysiological methods, and strategies for assessing the family context (Turk and Melzack 2001). As early as the late 1960s, data began to emerge that supported the effectiveness of psychological interventions for persistent pain, either in the context of multidisciplinary pain programs or in isolation of other interventions. A range of specific psychological interventions have considerable support for their efficacy including cognitive-behavioral interventions, as well as self-regulatory interventions such as relaxation training, hypnosis, and biofeedback. Research has documented the benefits of various psychological interventions for such pain conditions as headache (Holroyd et al. 2001), low back (Hoffman et al. 2007), and arthritis (Keefe et al. 2002), among many others. One particularly influential meta-analysis of the cost-effectiveness of multidisciplinary pain care, published by Flor and her colleagues, documented the benefits of such programs on pain and functioning, including return to work (Flor and Fydrich 1992). A recent line of investigation has begun to focus on identification of predictors of change during pain treatment, the process of change, and the potential to improve outcomes through a process of matching individual characteristics with different treatments (Turk and Okifuji 2002, Kerns and Habib 2004). Although not specifically attributable to the contributions of a behavioral medicine perspective, research has informed an approach to practice and policy that encourages identification of psychiatric comorbidities and concurrent pharmaco logical and psychological management of common mood and anxiety disorders.

Cancer
Psychooncology is a rich area for behavioral health practitioners as cancer is typically a frightening prospect. No matter how benign the course may appear, the general cultural imagery of cancer—with the implications of death and disability, combined with the shame and stigma—places cancer among the most dreaded human illnesses. The uncertainty of outcome and treatment combined with a potentially disfiguring or fatal illness is alarming. Distress and defensiveness of threatened mortality becomes a part of the medical situation with a diagnosis of cancer. These reactions are based on the patient’s personality style, characteristic coping mechanisms, and/or cultural beliefs—all of which can be exacerbated by misinformation and fear. There is much work for the skilled and interested mental health professional in this setting.

One of the great debates has been the relationship between the onset and course of cancer and associated psychopathological states and/or characteristics. Currently, there is little evidence that particular psychopathological states precede cancer in a predictable fashion (Hahn and Petitti 1988, Dattore et al. 1980). Furthermore, there is little evidence that stress or stressful life events have any relationship to the onset of various cancers (Fox 1983).

The value placed on psychosocial care has recently shifted: The current clinical research is less focused on internal qualities of the patients that may contribute to the course of cancer treatment and more focused on identified behavioral risk factors such as smoking cessation and sunscreen use. As a result, research findings have been more promising. Holland (2004) notes that the influx of behavioral medicine in the 1970s brought a new group of researchers to psychosocial care with a desire to examine lifestyle changes and the impact of nursing care on palliative care. Clearly, certain behaviors increase the risk of developing cancer, tobacco use being among the most notable. Psychological treatments aimed toward lifestyle modification have been effective. Supportive group therapy has also demonstrated success in positively influencing important dimensions of the cancer experience, especially with respect to improvements in the quality of life and treatment response for cancer patients as well as decreased pain and distress (Spiegel and Bloom 1989, Groth-Marnat and Schumaker 1995, Fawzy and Cousins 1990).

Cancer impinges on the mental state of patients in several different ways including experiences of shock, worry, and demoralization that can evolve into subsequent depression and/or anxiety (Derogatis et al. 1985). Some people respond to the impending knowledge that something is wrong by denying illness and delaying seeking medical help (Facione 1992). In some, the risk of suicide is increased in the early stages (Harris and Barracough 1995). Major depression can occur throughout the course of the illness, affecting 10–68% of patients (Harris and Barracough 1995, Noyes and Kathol 1986). Such variation is a function of the heterogeneity of cancer and higher rates associated with specific cancers. However, the overall prevalence for depression in cancer patients is around 30%. Among patients who develop depression, antidepressant medications are extremely helpful. However, medication metabolism in the cancer patient with multiple treatments are particularly prone to alterations of enzyme inhibitory systems due to concurrent use of other agents (Kalash 1998).

A big part of the cancer care also involves providing appropriate communication, understanding, reassurance, consolation, practical assistance, emotional support, information, direction, and psychological treatment. This care is given by all members of the treatment team according to his/her role with the patient and the practitioner’s skill level, according to established guidelines (Turner et al. 2005). Interventions such as CBT and IPT have also been used effectively for the treatment of depression and anxiety among patients with cancer (Noyes and Kathol 1986, Holland and Reznik 2005, Sellick and Crooks 1999). Sometimes the complications of treatment can include mental status changes associated with the toxic agents of treatment, and sedating and tranquilizing medications can be an extremely helpful intervention as the patient and family members negotiate the disorientation of delirium (Eakin and Strycker 2001).

Unfortunately, some patients with cancer may have difficulty using available services. Eakin and Strycker note that while difficulties can be related to having adequate support, it is more often the case that the patient’s educational status, the nature of the existing referral and current social supports, the degree of discrepancies between patient and provider perspectives on support services, and patient’s level of spirituality influence how successfully the patient is able to access care (Eakin and Strycker 2001). For instance, the providers reported referring approximately 70% of their patients to cancer support services, while only 24% of the
patients reported that their physicians mentioned any such support services. Providers also estimated that 40% of the patients actually used support services; however, less than 10% of patients actually used these services.

Folkman and Greer have proposed a theoretical orientation of promoting psychological well-being in the face of serious illness in which all practitioners treating individuals who are coping with a serious illness are encouraged to address not only psychiatric symptoms and/or emotional distress, but also psychological well-being (Folkman and Greer 2000). They provide several practical guidelines, such as creating conditions for challenge by finding out what is meaningful and matters to the patient, and then identifying relevant and obtainable goals by emphasizing opportunities for personal control. Encouragement of goal-directed behavior is also highlighted in their recommendations. Finally, it is important to maintain an environment that supports a positive mood: In a review of 44 empirical studies of cancer support groups, the high levels of patient satisfaction, high morale and other quality of life benefits short of prolonging life have been demonstrated (Gottlieb and Wachala 2006).

The two major barriers to the treatment of depression and cancer are cost and uncertainty; however, structural strategies to improve depression care in cancer patients include nursing interventions and telephone monitoring, depression screening and education, targeted prevention, development of guidelines and policy. Curiously, the importance of co-location of behavioral health services in a cancer setting has not been emphasized (Greenberg 2004).

The experience of the treatment of cancer can also have associated behavioral and psychological symptoms, sometimes leading to specific diagnoses. At times, the treatments themselves physically cause these symptoms. Radiotherapy and various forms of infusion chemotherapy certainly cause nausea, vomiting, fatigue, anhedonia, and malaise. The disfiguration—such as the mutilating aspects of surgical solutions such as mastectomy and head and neck surgery—can clearly contribute to emotional distress. In addition, interferon associated with dramatic responses has been associated with delirium (Rosenstein et al. 1999).

Sometimes the illness itself causes changes in mental state. This can be from direct impingement of the tumor in the case of central nervous system lesions or the effect of metastases, either directly into the central nervous system, or secondarily, into organs that influence CNS function, such as endocrine functions. Obviously, providers must pay attention to the needs of the family members of a person who has cancer; particularly if the identified patient is a child living with parents (Mitchel et al. 2006).

Genetic Counseling and Cancer

Meiser (2005) reviews the literature on the psychological impact of counseling of patients for hereditary breast and ovarian cancer as well as hereditary forms of colorectal cancer and adenomatous polyposis and concludes that noncarriers obtain considerable benefit from the knowledge derived from the testing and that for carriers they also obtain benefit but their response is filtered through their former experience with cancer. Overall, among people attending family cancer clinics, about 50% opt for genetic testing but the number goes closer to 80% in some settings.

Organization of Services and Cancer

Behavioral health services are provided by many members of the clinical team depending on expertise and role (Holland 2004, Spiegel and Bloom 1989, Holland and Reznik 2005, Folkman and Greer 2000, Mitchel et al. 2006, Thomas et al. 2004, Grossarth-Matieck and Schmidt 1984). Specialty services are best organized in such a way so that patients experience the mental health treatment as an integral part of the treatment rather than a separate aspect of treatment. Holland makes the point that patients are much more likely to feel a double stigma of cancer and mental illness if they have to go somewhere else for the treatment of the depression or anxiety associated with their circumstance of cancer.

Some Other Multidisciplinary Approaches

Palliative Care

Palliative care grew out of the hospice movement most likely initiated by Dame Cicely Saunders, the founder of St. Christopher’s Hospice near London in the 1940s. In America, the hospice movement began in Branford, Connecticut, in 1974. Since then, the notion of palliative care gradually entered into mainstream hospital care, propelled along by a variety of patient autonomy issues, such as DNR directives, the physician assisted suicide movement, and the specialization of medicine that requires expertise in providing the care of comfort as well as the care of cure. According to the American Board of Psychiatrists and Neurologists, palliative care is a recognized subspecialty that requires additional training and qualifications. Nonetheless, the establishment of palliative care units has faced ongoing challenges largely due to anticipated costs and budgetary limitations. The well-publicized report in the Wall Street Journal that cited reduced total costs associated with palliative care in an academic medical center has sparked heightened interest (Naik 2004). Currently, there are several professional organizations affiliated with palliative care, including the International Association of Hospice and Palliative Care (http://www.hospicecare.com), the National Hospice and Palliative Care Organization (http://nhpco.org), and the Center to Advance Palliative Care (http://www.capc.org).

Palliative care is defined as the provision of comfort and the improvement of quality of life in the context of an illness in which cure is no longer possible or sought. The emphasis of care is on the relief of symptoms and the resolution of existential crises through reassurance, spiritual counseling, and the provision of sound medical care. Patients receiving palliative care often exhibit a wide range of physical symptoms related to their terminal illnesses—such as pain, delirium, fatigue, dysphagia, incontinence—that have profound psychological consequences for themselves, their families, and their caregivers. Moreover, it is estimated that 20–50% of patients receiving palliative care have a comorbid psychiatric condition, with increased rates of emotional distress noted especially among individuals who are experiencing significant pain and among individuals in the more advanced stages of their progressive terminal illnesses. Common psychiatric concerns include adjustment disorders, depression, anxiety, delirium, and other cognitive disorders (Gibson et al. 2006).
Surgeon General’s Report on Mental Illness

This report recognizes the inextricable, intertwined relationship between our mental health and our physical health and wellbeing. The report emphasizes that mental health and mental illnesses are important concerns at all ages. Accordingly, we will continue to attend to needs that occur across the lifespan, from the youngest child to the oldest among us (US Department of Health and Human Services 1999).

Palliative care is a multidisciplinary approach that involves various types of healthcare specialists who share a solid commitment to clear, genuine communication during the final stages of life (Fins 2000). In addition to addressing physical discomfort and psychological distress, spiritual support is oftentimes a key component of preparing for end-of-life transitions and often provided by religious ministers who serve on the palliative care team (Ferrell 2005, Chochinov and Cann 2005). In these instances, the intense feelings that patients and their loved ones experience are not necessarily signs of psychopathology, but rather normal emotions and feelings such as fear, grief, and loss. As the patient and the patient’s family deal with death, the consideration of “a good death”—meaning dying with dignity, with appropriate palliative measures, and being supported by loved ones—becomes more prominent (Chochinov 2000, Lyness 2004, Chochinov 2006). Within this context, existential issues related to the limitations of one’s life frequently need to be addressed. Patients must be assisted to come to terms with the meaning of their lives and to try to reconcile any differences or problems with their family and friends.

Integration of Mental Health into Primary Care Settings

One of the more recent initiatives within the field of behavioral medicine, integrating mental health services into primary care settings is the result of efforts of the Surgeon General who published The first Surgeon General’s Report on Mental Illness in 1999, Dr. David Satcher (US Department of Health and Human Services 1999).

This landmark report includes several key features. First, it takes the somewhat provocative stance that mental and physical health concerns are interrelated. Moreover, efforts to separate the mind from the body are not only oversimplistic, but misguided. Second, this report emphasizes that mental illnesses are genuine health concerns with significant negative effects both for the individual and for society at large. Nonetheless, it explicitly recognizes the wide range of effective treatments for most mental health concerns and the unfortunate fact that many Americans do not obtain such treatment. The report ends with a call to action to resolve the myriad barriers that prohibit individuals from obtaining needed mental health services (US Department of Health and Human Services 1999).

One response to this call to action was the 2000 Surgeon General’s Working Meeting on the integration of mental health services and primary healthcare (DHHS 2001). Prevalence estimates suggest that at least 25% of patients who seek primary care services also meet criteria for a psychiatric illness (Barrett et al. 1998, Olsson et al. 1997) and approximately 70–80% of all primary care visits address mental health concerns as a primary or secondary complaint (Von Korff et al. 1998, Von Korff and Simon 1996). It is clear that primary care providers are “a critical link” (US Department of Health and Human Services 1999) in pioneering efforts to identify and treat a broad spectrum of mental disorders.

Clearly, the integration of mental health resources within primary care settings represents a revolutionary, cutting-edge opportunity for behavioral medicine to address the recurrent mental health needs often seen in primary care settings. Most recently, the White River Junction model has been commended not only for its progressive integration of a full range of behavioral health interventions within a VA primary care setting, but also for its ability to demonstrate increased overall access to mental health services through integration (US Department of Health and Human Services 1999). The basic premise of this model includes embedding mental health providers within primary care clinics who could provide immediate access to psychiatric services for patients with a wide range of mental health concerns. Similar approaches have demonstrated improved outcomes for addressing depression and alcohol use issues treated through integrated, collaborative approaches as well as a sense of overall decreased stigmatization of their mental health concerns and increased success with mental health screenings (Bartels et al. 2004). Such increased efforts to address depression are taking hold within primary care settings and with just cause: Depression is often present among 6 out of every 10 patients seen within a primary care setting yet often unrecognized by primary care practitioners (Katon and Schulberg 1997). In fact, the majority of individuals with depression receive treatment outside the traditional mental health environment and within primary care clinics (Coyne et al. 1994, Reiger et al. 1993). This finding alone suggests that increased efforts to identify depression within the primary care setting will likely lead to improvements in treatment (Pignone et al. 2002).

Technology in the Future of Behavioral Medicine

The proliferation of technology in the home, workplace, and a wide range of public settings is evident, especially within highly industrialized nations. Undoubtedly, such technology is becoming ever-present within the healthcare system and can influence—directly and indirectly—health...
and wellness. A comprehensive overview of the impact of technology on behavioral medicine is beyond the scope of this chapter; however, we present a brief introduction to a particular example of the use of technology within the field of behavioral medicine to illustrate some of the promise of the new technology.

One particularly timely and relevant example is the use of Geographic Information Systems (GIS) within behavioral medicine. GIS is a technological tool for linking environmental, social, behavioral, and health-related data for more meaningful interpretation. As a result, findings can be displayed not only by traditional numerical and statistical methods (e.g., frequency tables, means, standard deviations, etc.) but also within a graphical representation of their physical surroundings. For example, intersections that are prone to automobile accidents can be displayed on a map that also accounts for the frequency of such accidents per site. The impact of this type of graphical data representation for health promotion is highly promising due to the inherent parsimony. Extending the same automobile accident example, GIS data can be used to monitor driving behavior, educate the general public, inform legislation and public policy, as well as guide community-based health promotion interventions (Thomas 2007).

Similarly, ecological momentary assessment (EMA) is another example of the use of technology in behavioral medicine. EMA is an in vivo technique for obtaining self-report data that employs specialized software specifically designed to interface with existing technological devices—such as personal digital assistants, cellular phones, or similar electronic devices. Compared to existing mechanisms for obtaining self-report data, data obtained through EMA is believed to be more timely, more accurate, and less susceptible to recall bias and faked compliance (Cooney 2006). Although EMA has only recently been incorporated into behavioral medicine research, the promise for further development of technology to promote health and behavior in research and clinical settings remains strong.

The Practice of Behavioral Medicine

Clinical Evaluation and Interviewing

The evaluation in behavioral medicine will include examination and history as in other healthcare areas, but a broad view of the history of the patient in context will be taken (Blumenfeld and Strain 2006, Levenson 2004). The patients’ spontaneous accounts frequently are complex and may not initially reveal a full history. The behavioral medicine specialist will be interested not only in symptoms but also in the circumstances in which they occur and the psychological, behavioral, and social responses they elicit. Understanding the patient’s view of his diagnosis and treatment may be important in securing full adherence with treatment. Collateral information from family will help to reconstruct the context of the patient’s illness and to understand the patient’s function in the real world. The evaluation will include behaviors with delayed but important long-term health consequences, such as smoking or exercise. The evaluation in behavioral medicine will examine aspects of medical history that receive inadequate attention from our crisis-oriented healthcare system. A full evaluation is a basis for correct diagnosis and treatment, but also reassures the patient that he has been heard. This may be a critical first step in treating the difficult or somatizing patient.

The evaluation will likely require the review of medical records and contact with other healthcare providers. Past medical records may be needed to complete a complicated history or verify diagnostic results and treatment. Patients may report a positive diagnosis that in fact was negative or ambivalent, or conversely a positive diagnosis may have been missed. A history of repeated unexplained symptoms or repeated doctor visits may reveal a somatizing or factitious diagnosis. Contacting other healthcare providers may be essential in clarifying the history, and also in understanding the interaction of the patient and the healthcare system, which is a key domain in behavioral medicine. The consultant will need to obtain consent required by local or national laws. The provisions of the Health Insurance Portability and Accountability Act (HIPAA) of 1996 have eased restrictions on the exchange of information among current providers (Hodge 2003). It is advisable to clarify with the patient at the outset that effective care can be provided only with free communication among all providers of care and to seek the patient’s consent to freely share clinical information.

A broad view of the patient and his context is also essential because the behavioral medicine specialist is often called upon to diagnose and treat not only the patient but also his interaction with the healthcare system. The behavioral medicine specialist may need to be sure that all healthcare providers are aware of each other, the full medical history, and the treatments they are pursuing. He may need to detect and repair problems in communication among the patient and providers. The behavioral medicine specialist may be the healthcare provider best able to assess the patient as a part of a larger system and should play an assertive role in working with other providers to coordinate his patient’s care.

In addition to assessment of the patient, the attitude and approach of the clinician is important. Recently, the concept of mindfulness has been brought forward by Epstein. Mindfulness skills can help the behavioral medicine specialist listen attentively to the patient’s pain and suffering, make evidence-based decisions, and clarify values and assumptions. Epstein (1999) conceptualizes mindfulness as being willing to examine and set aside categories and prejudices and instead to approach situations with a “beginner’s mind.” The characteristics of mindful practice include active observation of oneself and the patient within the social context; an ability to draw on “peripheral vision” and feelings, thoughts, and memories just below consciousness and just outside of attention; and critical curiosity and courage to see the world in its reality rather than what one hopes or wishes it to be. The mindful practitioner is able to attend to his or her own mental processes in a neutral fashion during the everyday job of caretaking. While mindful practice is fundamentally invisible, it nonetheless allows the practitioner to react to the patient’s condition with a robust and empathically accurate understanding and provides additional rich information about the patient’s experience. In this context, the mindful practitioner is able to make evidence-based decisions consistent with the values of the patient as well as the practitioner; values that entail compassion, insight, and adherence in a flexible fashion, to the role of the physician healer.
Clinical Assessment and Use of Self-Report Devices

It is not surprising that reliable assessment of key constructs looms large in the field of behavioral medicine given its historical and contemporary roots in behaviorism and cognitive-social learning theory and the emphasis of these perspectives on quantification and measurement. The enormous array of assessment strategies that have been developed for use in clinical and research settings reflect the interdisciplinary nature of the field, its emphasis on the biopsychosocial model and interacting systems, the multiple theoretical and clinical perspectives that inform the field, and its broad scope. A comprehensive review of even the most commonly employed strategies is well beyond the reaches of this chapter.

Central to assessment in behavioral medicine is a keen awareness that health, disease, and illness are ambiguous concepts that vary in meaning and experience that often have little to do with “objective” physical evidence (Mechanic 1968). Given this assumption, it may seem obvious that efforts to improve the reliable measurement of constructs that are critical to the field of medicine, such as symptoms, stress, and adherence, among enumerable others, are critically important. Crucial to investigation and clinical assessment is the ability to develop sensitive strategies that will (1) delineate individual and group differences and (2) assess factors that potentially mediate or moderate these differences (Turk and Kerns 1985). Much of the development of assessment strategies in the field of behavioral medicine has been specifically informed by these goals.

Consistent with an interdisciplinary field, assessment in behavioral medicine encompasses strategies that are most consistent with specific disciplines and research and clinical methodologies commonly employed within these disciplines. The fields of epidemiology and public health, for example, have contributed to the development of a broad array of specific tools and general strategies for the assessment of psychosocial epidemiology and health-related quality of life. The field of psychophysiology continues to contribute increasingly sophisticated and precise strategies for the detection, amplification, and quantification of physiological systems including, most importantly, the functioning of the central and peripheral nervous system. Sociology, social ecology, social psychology, and family medicine have played critically important roles in drawing attention to the measurement of context, including the structure and function of family, community, and other social networks.

Dominating the field are assessment strategies informed by clinical (health) psychology’s roots in development of reliable tests and measures. Although few would argue that the primary and “gold standard” assessment strategy in behavioral medicine settings remains the clinical interview, the use of self-report strategies such as questionnaires, inventories, and diaries and other self-monitoring procedures are commonly used to supplement the interview in many clinical settings, and these strategies are often the preferred methods in research settings due to their emphasis on quantification, brevity, face validity, and ease of use. Methods for the direct observation of health-relevant behaviors have also been developed primarily for use in research settings, although some of these strategies, such as those used by nursing staff for the assessment of pain among persons with severe dementia or others who are unable to orally communicate, are increasingly utilized.

Commonly employed self-report strategies continue to include measures originally developed outside the field of behavioral medicine for use with general populations such as the Minnesota Multiphasic Personality Inventory and the Beck Depression Inventory. However, the past 30 years have seen the proliferation and increasing use of health-specific measurement strategies that were developed for addressing behavioral medicine questions and problems and were validated using specific populations experiencing the problem. This large group of health-relevant measures can be further classified as either standardized measures for use in clinical settings versus those that were developed solely for research purposes, and those that are enduring personality (trait-like) measures and those that are situation-specific (state-like) measures. For example, in the area of pain management, a large array of measurement strategies has been developed specifically for use in measuring factors important in characterizing individual differences in persons with persistent pain (e.g., measures of pain severity or pain-related disability) as well as hypothesized mediators of these experiences (e.g., pain coping, pain-related self-efficacy). In this context, several well-validated self-report questionnaires and inventories are available for the assessment of the multidimensional nature of pain (e.g., the West Haven, Yale Multidimensional Pain Inventory (Kerns et al. 1985)).

Biofeedback

In the late 1960s and early 1970s, Neil E. Miller (1978) made what was at the time quite a controversial and provocative claim: A person could learn to control behaviors—such as breathing, heart rate, and other automatic physiological responses—that were under the control of the autonomic nervous system. Such a claim drew expected criticism until research on what would later be called biofeedback provided the necessary supporting empirical evidence.

Biofeedback is based on operant-reinforcement principles applied to automatic musculoskeletal responses. A feedback signal—such as a light or sound—alerts the participant if the physiological parameter under investigation is within expected parameters. Over a series of successive trials, individuals gradually gain control over the selected physiological responses and can eventually elicit the desired physiological response upon demand. Early studies on biofeedback demonstrated its clinical utility in promoting deep muscle relaxation and other autonomic responses (Budzinski and Stoyva 1969, Thornton and Van Toller 1973, Taub and Emurian 1976). Biofeedback remains a viable modality of treatment for a wide range of health issues including asthma (Lehrer 1998), arthritis (Astin et al. 2002), chronic pain (Teunissen et al. 2004), and headaches (Rains et al. 2005). While a comprehensive review of the efficacy of biofeedback across various health concerns is beyond the scope of this chapter, it is important to note that empirical studies and reviews continue to provide evidence in support of biofeedback. For example, biofeedback has been demonstrated to reduce incontinence among the elderly by over 80% and achieved significantly better outcomes than medications (oxybutynin, which lead to a 68% reduction in incontinence) or placebo (Teunissen et al. 2004). Similarly, a comprehensive review of treatments for pediatric migraines
reveals that biofeedback—used alone or in conjunction with other behavioral strategies, such as progressive muscle relaxation—is superior to all other treatment modalities including calcium channel blockers, serotonergic medications, and other pharmacological interventions (Hermann et al. 1995).

Psychotherapeutic Interventions
As mentioned briefly throughout the previous section of this chapter, there is a wide variety of behavioral and psychotherapeutic interventions that can be beneficial in promoting health behavior change. These include approaches such as motivational interviewing (Miller and Rollnick 2002), traditional psychotherapeutic approaches such as cognitive, behavioral, and CBTs (Wolpe 1997), which have been beneficial across a wide range of health conditions such as somatiform disorders (Kroenke and Swindle 2000), chronic pain (Heapy et al. 2005, Reid et al. 2003), insomnia (Zhdanova 2004), as well as improving adherence of medical treatment (Dyer et al. 2005) as well as overall health and wellness (Grossman et al. 2004). This is in addition to the use of these modalities in the treatment of depression and anxiety co-occurring with cancer and HIV/AIDS as noted above.

Psychiatric Training in Behavioral Medicine
In 1987 training requirements in consultation–liaison (CL) were instituted for all psychiatry residency programs in the United States. At this time, all such programs must include at least 2 months of full time training in CL psychiatry, and certainly in all programs residents will receive additional training in the interplay of medical and psychiatric conditions throughout. In 2002 CL psychiatry was recognized by the American Board of Medical Specialties as a subspecialty of psychiatry. Trainees must complete one year of postresidency fellowship training meeting specific standards established by the American Council on Graduate Medical Education, and pass a written examination in the field. The name chosen for the subspecialty, Psychosomatic Medicine, has been controversial. However controversial the new term may be, it does acknowledge the inextricable link of psyche and soma in human health.

The Application of Behavioral Medicine: A Case of Chronic Pain
The case of FL is taken from the seminal paper by Blumer and Heilbronn (1982) in which they offered a compelling articulation of a prevailing model of the time of chronic pain of uncertain origin as a variant of depressive disease, sometimes referred to as “masked depression.” According to this framework, and informed by prior descriptions in the clinical and theoretical literature, these authors suggest that once efforts to identify a neurological basis for complaints of pain have failed, and instead of invoking a stigmatizing label of “psychogenic disorder,” Blumer and Heilbronn proposed the diagnosis of a depressive variant, the authors encouraged treatment with antidepressants and behavioral modification designed to promote increased functional activity.

The case of FL provides an opportunity to consider how the various theoretical approaches described earlier might be applied clinically to assess and treat this patient from a contemporary behavioral medicine perspective as briefly described in previous sections of this chapter. From data to support their conceptualization. Consistent with the diagnosis of a depressive variant, the authors encouraged treatment with antidepressants and behavioral modification designed to promote increased functional activity.

At 18 years of age, FL began working in an automobile factory. He regularly worked 10–16 hours a day, often 6 days a week. At 20 years of age he was married and the couple had a son. At 22 years of age, FL began to experience pain in his back, legs, and neck. The patient was no longer able to work… He was referred at 24 years of age, after being in continuous pain for 2 years and expressed considerable hostile feelings about his job, stating that for nearly a year he “wanted to kill when it was not necessary,” explaining that he wanted to do away with the foreman who supervised his work. FL felt that his employers and their physician did not take his illness seriously. FL stated that he had no difficulties getting along with other people…[However], he and his wife were feeling financially stressed. He was using no medication, but reported that he was afforded some relief from his pain when his consciousness occupied his “astral body.” He was prescribed amitriptyline and after 1 month reported feeling better but continued to focus on his inability to work. With encouragement, he was able to return to his job for nearly 2 months. He soon began having “heart pain” and was concerned regarding the effect the vapors in his work environment had upon his health. He independently increased his daily dosage of amitriptyline from 300 to 500 mg daily. He began having abdominal pain as well which ended up in his having gallbladder surgery. About 6 weeks following his surgery, he returned to work for a couple of weeks but stopped reporting for work when he found his persistent abdominal pain intolerable. He stayed in treatment for the next 2 1/2 years but was never able to return to work… At 26 years of age, FL became a father for the second time. Shortly thereafter, he and his wife had frequent, heated arguments over their mounting financial problems; the fights later became laden with threats and physical abuse. Thioridazine was added to his antidepressant regime; however FL failed to use the drugs properly or regularly. He began drinking a pint of scotch daily in addition to using marijuana and cocaine… He continued to be volatile and abusive toward his wife… In the interim, his wife had obtained employment at a restaurant and left FL the following month, taking the children with her.

Source: Adapted from Blumer and Heilbronn (1982) (pp 402–403).
the onset, the biopsychosocial perspective on pain and pain management would have been used to inform a comprehensive pain assessment of FL designed to develop an integrative, multidisciplinary plan of care. Certainly, prior to engaging in psychological or psychiatric treatment of a “pain disorder,” appropriate medical/neurological evaluation of his pain complaints is indicated and should include a detailed history, including attention to the psychosocial and cultural context, and a targeted physical and neurological examination. In the absence of any medical “red flags” indicating the potential presence of infection, fracture, or malignancy, no further medical diagnostic procedures would probably be indicated.

Given the presence of significant emotional distress and apparent functional decline, a comprehensive psychological assessment appeared to be appropriate. This assessment would almost certainly rely heavily on an extensive interview designed to identify the range of negative functional and emotional impacts of his experience of pain and to begin to engage FL in an open consideration of the possible role of similar variables as contributors to his experience of pain, disability, and distress. In addition to an elicitation of detailed description of FL’s experience of pain, the interview would attempt to capture a behaviorally specific understanding of his current level of physical functioning including activities of daily living and the broader array of social and recreational functioning. Specific attention to his negative emotional experiences would almost certainly be an important focus of the interview, including efforts to identify the presence of Axis I and II disorders common among persons with persistent pain such as depression, anxiety, and substance use disorders. Candidate contributing variables include the range of psychological factors described in the earlier review including negative cognition (e.g., pain catastrophizing), fear avoidance, low self-efficacy and perceptions of a lack of self-control, and passive coping, among other factors. Responses of significant others, particularly his wife and friends, to his complaints of pain would specifically be assessed, and ideally, the involvement of his wife in this discussion would be secured.

In many settings, extensive interviewing would be supplemented by the administration of a range of standardized psychological questionnaires and inventories that have been validated for use in the assessment of persons with chronic pain. Often included in this battery are measures of pain intensity and quality, pain-related interference, emotional functioning, health-related quality of life, as well as measures of the range of potentially relevant psychosocial factors described above. These measures are important for efficient and reliable assessment of numerous psychological factors that are potentially relevant for informing the treatment plan, for deriving quantitative indices of potential targets for intervention, and in developing a baseline for future evaluation of treatment efficacy. Less frequently, diaries for self-monitoring of pain intensity, mood, activity, and other variables are used to further supplement the interview and questionnaires.

Ultimately, the goal of the psychosocial assessment is the development of an integrative conceptualization of FL’s experience of pain, disability, and distress and the potential relevance of a range of psychological and interpersonal factors that may be serving to perpetuate this experience. In the case of FL, a more “here and now” focus on his current reports of severe pain, his withdrawal from many previously enjoyable and productive activities, his pervasive anger, and growing tensions in his marriage would serve as primary targets for intervention. Although, the description by Blumer and Heilbronn leaves unclear the most salient psychological and interpersonal contributors to these negative outcomes, the presence of pervasive feelings of helplessness and hopelessness, low self-efficacy and lack of self-control, passive and avoidant coping, and an unsupportive spouse are likely contributing factors.

State-of-the-art treatment for someone with FL’s history and presenting problems would incorporate aspects of virtually each of the models in the specification of an integrated, multidisciplinary, and multidimensional plan for rehabilitation (Turk and Gatchel 2002). The specific design of the intervention would be informed by a comprehensive pain assessment based on theory-driven research that has led to the identification of common psychosocial contributors to the experience of pain, disability, emotional distress, and poor health-related quality of life (Turk and Melzack 2001). Empirical support for multidisciplinary treatment for chronic pain—especially the inclusion of psychological interventions as a key component—is strong and compelling (Hoffman et al. 2007, Flor and Fydrich 1992).

Fordyce’s (Fordyce 1973, Fordyce et al. 1973) operant behavioral model is instrumental in promoting a consideration of behavioral factors and the role of social learning in the perpetuation and development of chronic pain. Fordyce hypothesized an important reinforcing role of environmental responses (e.g., expressions of sympathy from family members, attention from healthcare providers, release from work and household responsibilities, financial compensation) contingent on displays of pain and infirmity termed “pain behaviors” (e.g., complaints of pain, facial grimacing, distorted ambulation, withdrawal from activities, use of pain medications) in maintaining pain and pain-related disability in the absence of continued nociception. His model informs research investigating the role of social learning in fostering pain and interventions to shift the delivery of reinforcement to “well behaviors” such as exercise, return to work, and reduction of reliance on pain medications, and increased social, recreational, and other productive activities. A treatment approach for FL informed by the operant behavioral perspective would emphasize the use of contingency management techniques to promote similar behavioral goals (Sanders 2002). For example, the clinician might offer praise whenever FL discusses examples of increased functioning and consciously avoid efforts that might inadvertently reinforce pain-related behaviors such as encouraging increased reliance on others for tasks that FL could reasonably perform independently. In fact, it is interesting to note that this component of a comprehensive plan is evidently similar to that described by Blumer and Heilbronn in their characterization of treatment for persons with a “pain-prone disorder.” For example, prior to engaging in outpatient treatment and after completion of a comprehensive pain assessment, FL and therapist would collaborate in the articulation of specific behavioral goals for treatment, including those just noted such as regular exercise and reduction of pain medications. Weekly intersession goals linked to these overarching treatment goals would be specified as “homework,” and plans for accomplishing the goals would be specified. Strategies for self-reinforcement
for goal accomplishment, and certainly praise from the therapist, would be important in effort to promote future action. Almost certainly, given the focus of the treatment on the responses from the social environment, this treatment would have encouraged explicit involvement of FL’s wife in an effort to promote more positive communication overall, decreased attention to pain behaviors, and increased cuing and praise for health-promoting goals of treatment.

CBT that specifically targeted idiosyncratic, negative beliefs about pain, particularly thoughts characterized as catastrophizing and consistent with a lack of personal control and low self-efficacy related to pain management would be prescribed for FL. CBT treatment would incorporate education and encouragement to adopt adaptive pain coping skills such as activity pacing, effective use of distraction, exercise, and stress management skills in either an individual or group format. Development of anger management skills would also be indicated. Biofeedback targeting muscle tension in the paraspinal muscles of the lower back and/or more electromyographic or thermal feedback assisted mental relaxation training might also be prescribed. Pharmacological interventions, physical therapy designed to promote proper body mechanics, muscle strengthening, and overall fitness, and vocational counseling would also be prescribed. Finally, given the extent of FL’s apparent problems with alcohol and other illicit substances, substance use treatment would be integrated into the overall treatment plan.

Summary and Conclusions
Behavioral medicine formally emerged as a distinct, multidisciplinary approach toward understanding health and illness following the 1977 Yale Conference. Building upon the biopsychosocial model, the field of behavioral medicine stands in contrast to previous historical efforts to understand health and human behavior—most notably mind-body dualism. Key experimental and theoretical advancements in the study of human behavior from the classical studies on behaviorism to more recent developments such as the TTM have been readily incorporated into the dynamic and expanding field of behavioral medicine. The theoretical, empirical, and clinical implications of behavioral medicine have proliferated at a rapid and impressive rate. It is clear that the field of behavioral medicine holds much promise for continued efforts to understand health, illness, and behavior.

Psychosocial Rehabilitation

Evidence accumulated over the last several decades has led to a general consensus that schizophrenia is a brain disease or set of related diseases caused by genetic and/or perinatal and perinatal insult (Roberts 1991, Weinberger 1987). Replicated data point to problems in neural structure (e.g., enlarged cerebral ventricles, hippocampus), neurotransmitter systems (including dopamine, serotonin, acetylcholine, and glutamate, among others), neural circuitry (e.g., especially including circuits mediated by frontal cortex), and cerebral blood flow and metabolism (especially in dorsolateral prefrontal cortex, cingulate gyrus) (Selemon 2001, Thaker and Carpenter 2001).

While the definitive neurological substrate of the illness remains to be determined, it is clear that treatment for schizophrenia must be based at least in part on effective psychopharmacological interventions. Conversely, no extant pharmacological treatment is sufficient. Twenty percent or more of people with the illness are not responsive to antipsychotic medication, and the majority, although responsive, have residual symptoms. In addition, many are substantially nonadherent. Even among those who are judged to be responsive and compliant, only a small proportion achieve adequate outcomes, including a return to premorbid levels of function. Schizophrenia is a multiply handicapping disorder marked by poor social role performance, chronic unemployment (or under-employment), excess medical morbidity and mortality, shortened life expectancy (including a markedly elevated risk for suicide), high levels of substance abuse, and increased risk for criminal victimization. Antipsychotic medications are demonstrably effective in reducing positive symptoms and have a modest effect on negative symptoms (especially on secondary negative symptoms), but they have limited impact on cognitive impairment and psychosocial functioning (Sharma and Harvey 2000). Even the new generation drugs are insufficient to restore premorbid levels of functioning, produce normative role performance, or substantially improve quality of life for most patients (Bellack et al. 2007).

Moreover, it seems highly unlikely that medication alone can be sufficient until and unless discoveries emanating from genetics and genomics lead to different and more effective compounds for pharmacotherapy. Accumulating evidence indicates that schizophrenia is a neurodevelopmental disorder in which many patients demonstrate subtle attentional, cognitive, and neuromotor abnormalities in early childhood, long before the onset of overt psychotic illness, in keeping with “neurodevelopmental” models of the illness (Cornblatt and Keilp 1994, Walker et al. 1994, Weinberger 1995). Perhaps the most remarkable investigation demonstrating this was performed by Jones and colleagues (1994) who followed up subjects originally studied as part of the Medical Research Council National Survey of Health and Development, a study of all births in England, Scotland, and Wales during 1 week in 1946. These children were assessed at multiple time points with measures of developmental milestones, educational achievement, and social-behavioral assessments. Of the 4746 English subjects, 30 developed schizophrenia by the age of 43, with cases identified and diagnosed on the basis of multiple medical record sources and direct interview data when subjects were aged 36. These subjects demonstrated delayed achievement of motor and speech milestones in infancy, lower estimated IQ scores by middle childhood, and increased social anxiety by early adolescence in comparison to the 4716 controls. These data suggest that adult schizophrenia is preceded by multiple manifestations of subtle developmental compromise across neurological, intellectual, and social domains.

The developmental consequences of the illness are magnified with the first psychotic episode in late adolescence or young adulthood. People with schizophrenia become progressively more removed from their peer group, fail to achieve (or sustain) adult milestones such as marriage, higher education, and employment, and often become socially isolated. These functional, psychosocial consequences become more severe and entrenched as illness duration increases, and result in multiple treatment needs that are superimposed on the neurobiological aspects of illness.
While innovative new medications could potentially ameliorate (or compensate for) some of the consequences of anomalous neural development, it is unlikely that any pharmacological approach could restore normal brain function. Furthermore, no medication could undo the lifelong consequences of impaired learning, failure to master adult developmental tasks, and social withdrawal. These impairments mandate a multifaceted approach to treatment that includes an array of psychosocial strategies, of which rehabilitation plays a key role (Bellack 2004). This conclusion is supported by a series of consensus treatment guidelines, including the Schizophrenia PORT (Lehman et al. 2004a), and guidelines from the American Psychiatric Association (Lehman et al. 2004b), and the Canadian Psychiatric Association (1998), among others.

In the following sections, critical issues involved in effective use of rehabilitation and other psychosocial interventions are discussed and brief reviews of the most promising approaches are provided. The term rehabilitation is not precisely defined in our field. It is generally used to imply a subcategory of psychosocial treatment in which there is an emphasis on teaching/training, rather than discussion, and the focus is primarily on behaviors and functioning, rather than on intrapsychic processes (thinking and feeling). Reference is made to psychosocial intervention when the issues have generality to the broader domain of psychological treatment.

**Issues in the Design of Psychosocial Interventions**

The potential benefits of psychosocial treatment are often not achieved in the community due to poor understanding of the special needs and liabilities of people with schizophrenia. Five factors need to be taken into account when implementing psychosocial interventions and evaluating the results: (1) timing and duration of treatment; (2) individual differences in treatment needs; (3) the role of the person in treatment; (4) the limitations imposed by impairments in information processing; and (5) the need to base interventions on a compensatory model.

**Timing and Duration of Treatment**

Schizophrenia is a chronic condition that frequently has devastating effects on many aspects of the person’s life and carries a high risk of suicide and other life-threatening conditions. The care of most people with the illness involves multiple efforts to reduce the frequency and severity of episodes and to reduce the overall morbidity and mortality of the disorder. Many individuals require comprehensive and continuous care over the course of their lives with no limits as to duration of treatment. Despite common agreement about the extent of chronicity and disability most research on psychosocial interventions has focused on time-limited strategies, typically in the range of 3 to 6 months. This treatment duration is generally guided more by the pragmatics of grant design than by an analysis of patient needs. Nevertheless, such brief treatments have been found to be helpful for achieving specific goals, such as teaching people how to discuss medication side effects with a physician, how to engage in safe sex, and how to communicate more effectively with family members. Research indicates that gains from such brief, focused treatments can be maintained over time (Bellack et al. 1984, Eckman et al. 1992). However, given the pervasive neurodevelopmental and psychosocial effects of the illness, these brief interventions are unlikely to produce broad-based improvement in overall functioning, or enduring changes in vulnerability to symptom exacerbations and relapse. Brief and highly focused rehabilitation programs designed to accomplish specific goals (e.g., to teach people how to negotiate with health care providers or to go grocery shopping) can be quite effective. However, most people with the illness will require intermittent booster treatment even for such circumscribed skills training programs, while others will need continuing support (e.g., prompting to perform activities of daily living) throughout their lives.

Unfortunately, the literature does not give much guidance in how to predict individual patient needs or systematically plan how long the course of rehabilitation treatment should be. Many community agencies have responded to this uncertainty by permanently enrolling people in day treatment. However, few individuals can, or do, actively participate in such endless treatment programs. They may come to the treatment center, especially if directed to do so by family members or residential managers, but that does not mean that they are actively participating or learning new skills. Our own experience, while not supported by data, strongly supports the use of time limited training curricula that address current needs and goals. The person may repeat a curriculum (e.g., begin a new 3–6-month period in social skills training) if she/he desires but this should be a mutual choice between the person and program that reflects continuing motivation and need, not a reflection of diagnosis or economics (e.g., agencies cannot bill unless the patient receives some intervention). This latter point relates to another issue addressed in the APA guidelines (Lehman et al. 2004b): timing of treatment. The guidelines contend that the illness transpires in three phases: (1) acute, during which the primary aim is to reduce acute symptoms; (2) stabilization, during which aims are to minimize likelihood of relapse, further reduce symptoms, and enhance adaptation in the community; and (3) stable, during which aims are to maintain or improve level of functioning and quality of life, while continuing to monitor. Rehabilitation is generally not applicable during acute stages of illness. With hospital stays often limited to a few days to one week there is little opportunity to conduct a systematic rehabilitation program, and acutely ill patients generally are unable to effectively participate in cognitive–behavioral interventions during this period.

The role for psychosocial treatment increases as the person becomes more stable and shifts from support and stress reduction to specific rehabilitation strategies such as social skills training and cognitive rehabilitation. This three stage model and associated treatment emphasis has good face validity. However, both the model and assumptions about shifting goals of psychosocial treatment are based more on anecdotal evidence and clinical assumptions than on empirical data. More research is needed on how to determine which treatments are best provided to which individuals at which times in their lives.

**Individual Differences in Treatment Needs**

Schizophrenia is a heterogeneous disorder, with wide variability in symptom presentation, severity, course, and
treatment response. Indeed, the term schizophrenia may be more applicable. This heterogeneity has been interpreted as reflecting either multiple etiologies or multiple disease entities (Carpenter et al. 1993, Tsuang et al. 1990). It also undoubtedly reflects the idiosyncratic impact of each person's environment and experiences throughout life, which influence both how the illness manifests itself and individual differences unrelated to the core illness (e.g., comorbid vulnerability to depression or substance abuse). For example, Mueser and colleagues (1991a) found that 50% of people with schizophrenia had persistent deficits in social skill over a 1-year period, while 11% did not differ from nonpatient controls, and the remainder showed variable performance. Thus, the common assumption that everyone with schizophrenia has significant social skill deficits is true for many but not all individuals.

Similar evidence of heterogeneity exists in regard to neuropsychological deficits. People with schizophrenia, as a group, perform very poorly on the Wisconsin Card Sorting Test (WCST) (Heaton 1981), a measure of prefrontal dysfunction. A group, perform very poorly on the Wisconsin Card Sorting Test (WCST) (Heaton 1981), a measure of prefrontal dysfunction. However, reports have documented relationships between poor outcome and prefrontal abnormality of brain morphology is not surprising; previous studies have found significant correlations between ventricular size and brain morphology. These results have also been consistent with findings in schizophrenia (Pearson et al. 1984, Vita et al. 1991, van Os et al. 1995). It is also noted that such differences may require very different services to achieve maximal independence than those who have much more intact cognitive performance.

However, it will not be possible to develop such services in an effective manner until we have achieved a clearer understanding of the determinants of disability in schizophrenia.

In addition to the variability between individuals, significant changes occur within people over time that have a bearing on treatment needs. Younger individuals need special help in dealing with the fact that they have a serious illness which may interfere with their personal goals and their ability to achieve independence, a problem that may contribute to their high vulnerability to suicide and substance abuse (Caldwell and Gottesman 1990, Test et al. 1989). Older people may adjust to the difficulties of the illness through withdrawal or positive coping strategies (Strauss 1989, Wing 1987), but they face unique problems of their own. For example, as parents grow older they are generally less able to continue caring for an offspring with schizophrenia, necessitating a shift in care taking responsibility to either siblings (Horwitz et al. 1992) or the mental health system. A survey of the needs of individuals with schizophrenia in regular contact with their families indicated that concern over what happens when a parent dies was ranked fourth highest out of 45 topics (parents ranked this concern fifth) (Mueser et al. 1992).

Taken together, these data underscore that treatment planning must be individualized. While this might seem like a given, many outpatient treatment systems are designed with a one-size-fits-all model, in which most individuals are assigned to a standard set of group treatments paired with case management. This is a strategy that maximizes dropouts and minimizes effectiveness. This is a population that is difficult to treat effectively under the best of circumstances. Positive outcomes are likely only if both the content of treatment and the format of treatment are tailored to the individual's needs and learning capacities.

The Role of the Person

The combination of psychosis, thought disorganization, and negative symptoms (especially anergia, apathy, and anhedonia) often lead to the false assumption that people with schizophrenia are not capable of being active participants in their own treatment. Indeed, many individuals seem unmotivated and are noncompliant, but such seeming disinterest and passivity should not be interpreted as accurate reflections of the person's goals and desires or as immutable traits. Negative symptoms are not always stable, and they may be secondary to demoralization, psychotic symptoms, medication side effects, and other factors that vary over time (Carpenter et al. 1988, McGlashan and Fenton 1992). A large number of trials and have clearly demonstrated that even extremely withdrawn, chronic persons can be motivated by systematic incentive (social learning) programs (Dickerson et al. 2005). Similarly, desire to change and inclination to do the work required for treatment also vary over time in the same way that motivation to lose weight or quit smoking varies in nonpatient populations.

The importance of developing a respectful, optimistic partnership between provider and consumer is clearly reflected in the consumer model of recovery and the
associated recovery movement (Bellack 2006). Over the past few decades a growing group of consumers, family members, and professionals have expressed increasing dissatisfaction with what has been seen as a paternalistic and unresponsive mental health system. At its most extreme, advocates of this consumer movement have seen traditional mental health services as iatrogenic, generating feelings of hopelessness and helplessness, promoting dependence, and fostering stigma. The more moderated view is that mental health professionals often fail to promote a sense of hope and optimism, to give consumers real choices, or to include consumers and family members as partners in the treatment process.

Two important reports from the US government provided considerable momentum to the recovery movement. First, the Surgeon General’s Report on Mental Health (1999) concluded that all mental health care should be consumer and family oriented and have the promotion of recovery as its primary aim. While this report did not have the force of law to produce changes, it served as a focal point for change among many state and municipal mental health systems, and stimulated discussion among advocacy organizations and the professional community.

The Surgeon General’s report was echoed more forcefully in the report of the President’s New Freedom Commission report: Achieving the promise: Transforming Mental Health Care in America (2003). Consistent with the recovery model, the New Freedom Commission report stated, First, services and treatments must be consumer and family centered, geared to give consumers real and meaningful choices about treatment options and providers (p 5). The report goes on to say, Consumers, along with service providers, will actively participate in designing and developing the systems of care in which they are involved. . . . In partnership with their health care providers, consumers and their families will play a larger role in managing the funding for their services (p 8).

The general recommendations about the structure of treatment and treatment systems in the Surgeon General’s and President’s New Freedom Commission reports were concretized in a recent consensus statement from the Substance Abuse and Mental Health Services Administration (SAMHSA) (2005). The statement identified 10 characteristics of effective recovery-oriented services.

**Self-direction:** consumers lead, control, exercise choice over, and determine their own path of recovery.

**Individualized and person-centered:** there are multiple pathways to recovery based on the individual person’s unique needs, preferences, and experiences.

**Empowerment:** consumers have the authority to exercise choices and make decisions that impact their lives and are educated and supported in so doing.

**Holistic:** recovery encompasses the varied aspects of an individual’s life including mind, body, spirit, and community.

**Nonlinear:** recovery is not a step-by-step process but one based on continual growth with occasional setbacks.

**Strengths-based:** recovery focuses on valuing and building on the multiple strengths, resiliency, coping abilities, inherent worth, and capabilities of individual.

**Peer support:** the invaluable role of mutual support in which consumers encourage one another in recovery is recognized and promoted.

**Respect:** community, systems, and societal acceptance and appreciation of consumers—including the protection of consumer rights and the elimination of discrimination and stigma—are crucial in achieving recovery.

**Responsibility:** consumers have personal responsibility for their own self-care and journeys of recovery.

**Hope:** recovery provides the essential and motivating message that people can and do overcome the barriers and obstacles that confront them.

The scientific literature on the prevalence of recovery as defined by consumers and on the factors that contribute to it is in its infancy. Consequently, it is not yet clear if recovery oriented care is simply good clinical care from the perspective of client satisfaction, or if it actually leads to better care vis-à-vis cooperation and outcomes. Nevertheless, combining the public and consumer mandate with the preliminary data that are available provides a strong argument for providing recovery oriented care and approaching treatment as a partnership in which each participant brings unique and valued elements to the process.

### Impairments in Information Processing

It is now well established that impaired information processing represents one of the most significant areas of dysfunction in schizophrenia. The illness is marked by neuropsychological deficits in multiple domains, including verbal memory, working memory, attention, speed of processing, abstract reasoning, and sensorimotor integration (Braff 1991, Green and Nuechterlein 1999). These deficits are highly related to social functioning and role performance in the community, as well as to performance in skills training programs (Green et al. 2000, Koren et al. 2006). For example, Mueser and colleagues (1991b) found that poor memory had a deleterious effect on learning in social skills training, while pretreatment symptomatology was unrelated to social skill acquisition. Kern and colleagues (1992) also found that memory impairment as well as poor sustained attention (on the Continuous Performance Test) was associated with decreased learning in social skills training.

A related issue concerns the impact of neurocognitive deficits on the generalization of treatment effects. A basic assumption of all psychotherapies is that skills acquired in treatment sessions must be transferred or generalized to the person’s natural environment. Yet, such generalization is contingent upon cognitive processes that are often disrupted in schizophrenia, especially “executive functions” mediated by the dorsolateral prefrontal cortex (Weinberger 1987). Several analog studies suggest that generalization is limited at best, even when explicitly programmed (Bellack et al. 2000, Tenhula et al. in press).

Unfortunately, clinical rehabilitation programs have lagged behind the experimental literature in this arena and neurocognitive deficits have not been addressed in a systematic manner. To be sure, most sophisticated rehabilitation programs do adjust the rate at which information is presented and the amount of detail or nuance provided. Allowance is also generally made for the need for repetition and regular review. However, these adjustments do not necessarily compensate for deficits in working memory and higher level executive processes. For example, there are impairments in the ability to perceive the continuity of experience.
over time and to plan behavior accordingly; that is, to see how past experiences relate to current circumstances, or how what is currently being discussed can be applied in the future (Hemsley 1996). This problem would interfere with the ability to utilize newly acquired skills at appropriate times, to pursue goals in a systematic manner, or to use past experience to solve the problem. Similarly, there are deficits in self-monitoring and error detection that limit the ability to self-correct behavior after errors (Koren et al. 2006). While there are strong data to document that rehabilitation programs are effective in teaching new behavior (Smith et al. 1996), the literature does not document that newly acquired skills are applied in the community. Even in cases where interventions result in better clinical outcomes, the data do not support the face valid assumption that changes are due to what has been taught. This point was amply illustrated in the Treatment Strategies in Schizophrenia Project, in which family treatment was associated with reduced relapse rates despite an absence of any change in communication patterns, the purported mechanism of change (Bellack et al. 2000). Determination of the mechanisms that mediate behavior change in the community is perhaps the greatest challenge facing the field over the next decade if we are to develop more effective treatments.

Adoption of a Compensatory Model

As indicated above, schizophrenia is a multiply handicapping disorder. It impacts on the ability to perform activities of daily living (ADLs) and the ability to fulfill social roles, including worker, homemaker, student, parent, and spouse; it increases the risk of substance abuse and disease, including HIV; and it interferes with performance of appropriate health care behaviors, including compliance with both medical and psychiatric treatment. A large proportion of individuals with schizophrenia also have residual psychotic symptoms and periodic exacerbations and they experience high levels of depression and anxiety. Overall, they suffer from poor quality of life. In light of this panoply of impairments, no single treatment is likely to have a sufficiently broad-based impact. This circumstance stands in marked contrast to less severe disorders such as unipolar depression and anxiety disorders in which a single intervention may be expected to produce substantial amelioration of the condition. Nevertheless, psychosocial treatments for schizophrenia have often been held to this same standard leading to the faulty conclusion that they are not effective.

A rehabilitation model, the primary focus of this chapter, is more appropriate than the standard treatment model as (1) it implies a narrower focus on specific skills and behaviors, and (2) it aims to improve functioning in specific areas, rather than eliminating or curing an entire condition. As indicated above, cognitive impairment is a central feature of the disorder; evident in childhood and progressing sharply with the onset of psychotic illness. It is reasonable to speculate that the impairments observed in ill adults are at least of two types: (1) those present from early in development; and (2) those that are related to chronic psychotic illness. The existence of such early, developmentally based impairments suggests that the concept of “premorbid” functioning in schizophrenia may no longer be tenable; rather, there is a prepsychotic period during which there is subtle evidence of the “morbid” process. Thus, the challenge confronting attempts at cognitive enhancement may not be restoration of function, but instead may be the development of critical competencies and strategies for coping with deficits.

Consistent with this hypothesis, a compensatory approach to treatment may be more appropriate than the restorative or reparative approach characteristic of most treatment programs. For example, rehabilitation for people with visual impairments involves teaching them to rely more on other senses, to use special appliances such as Braille keyboards, to use aides such as canes and guide dogs, and to systematically arrange their environment to minimize the need for sight. Success is achieved by improving independence, role functioning, and quality of life, not by restoring vision. Comparable rehabilitation programming is provided for stroke patients, individuals with paralysis, and amputees. Of note, these activist, goal oriented approaches are inconsistent with either the short-term up-and-out philosophy or the lifelong day care approach often seen in public mental health centers. Individuals receive ongoing support, but the support is oriented to skill development and solving problems in daily living, not restoration of premorbid functioning. Conversely, effective rehabilitation is neither infantilizing nor paternalistic; it is supportive, but it is also task and goal oriented.

Cognitive adaptation training (CAT) is a creative compensatory approach developed by Velligan and colleagues (2000, 2002). Case managers provide patients with home-based, compensatory environmental strategies to help structure the person’s living environment which maximizes the likelihood that she/he can complete requisite activities of daily living. Examples include posting reminders about appointments on the exit door from the apartment, listing items of clothing to be worn on the closet door, and placing medications in a location that makes it maximally likely that the patient will see it and be reminded to take it. Prompts and other environmental aides are individually tailored to the person’s level of apathy, disinhibition, and executive dysfunction. CAT can be administered in a time limited fashion, but may be a lifelong service for severely impaired patients. Velligan and colleagues found 9-months of CAT to be superior to an attention placebo and standard outpatient care on positive symptoms, negative symptoms, motivation, community functioning, global functioning, and incidence of rehospitalization. This is an excellent model for compensatory interventions, and warrants further study.

Rehabilitation Strategies

The following sections will briefly describe and evaluate the three types of rehabilitation programs that have had considerable clinical and heuristic impact on the field, and are generally regarded as evidence-based practices: social skills training, cognitive rehabilitation, and supported employment.

Social Skills Training

Social dysfunction is a defining characteristic of schizophrenia that is semi-independent of other domains of the illness (Lenzenweger et al. 1991, Strauss et al. 1974). Social functioning is also predictive of the course and outcome of the illness (Johnstone et al. 1990, McGlashan 1986). The most useful perspective for understanding social functioning and social dysfunction in the illness has been the “social skills model” (Bellack et al. 2004, Meier and Hope 1998).
Social skills are specific response capabilities necessary for effective performance. They include verbal response skills (e.g., the ability to start a conversation or to say “No” when needed), paralinguistic skills (e.g., use of appropriate voice volume and intonation), and nonverbal skills (e.g., appropriate use of gaze, hand gestures, and facial expressions). These skills tend to be stable over time and make a unique contribution to the performance of social roles and quality of life (Bellack et al. 1990a, 1990b, Mueser et al. 1991a). Increasing social competence and improving social role functioning has been a major focus of rehabilitation efforts for the past 25 years, and a well-developed technology for teaching social skills has been developed and empirically tested: social skills training (SST) (Bellack et al. 2004, Liberman 1995).

The basic technology for training social skills was developed in the 1970s and has not changed substantially in the intervening years. It is a highly structured educational procedure that is generally conducted in small groups. Complex social repertoires such as making friends and dating are broken down into steps or component elements such as maintaining eye contact and asking questions. People are first taught to perform the elements and then gradually learn to smoothly combine them. Each session has a specific focus such as how to initiate conversations with strangers and how to refuse an unreasonable request. Trainers are more like teachers than traditional therapists. They first give participants simple instructions about how the behavior is to be performed, then they model appropriate behavior in a simulated conversation, and then they engage participants in role playing of simulated social encounters as a vehicle for practicing new skills. The therapists provide social reinforcement after each role played response and shape improved performance.

The content of training programs is organized into teaching units or curricula, such as job interview skills, dating skills, and safe sex skills. Training can last from 4–8 sessions for a very circumscribed skill, to as long as 1–2 years for a comprehensive skills training program. Sessions are typically held 2–3 times per week. Training is structured to minimize demands on neurocognitive capacity, and extensive use is made of audiovisual aids such as hand outs, flip charts or white boards. There is frequent repetition and review in an attempt to produce overlearning, so responses can be elicited relatively automatically in the environment.

Bellack et al. (2004) have published a user-friendly SST manual that provides a detailed how-to for clinicians wishing to develop social skills programs in their facilities. Another variant that has been widely disseminated skills is the UCLA Social and Independent Living Skills Program (Liberman 1995). This program includes carefully crafted videotapes and instruction manuals for both trainers and participants. Training employees standard skills training techniques (e.g., role play, modeling) and includes modules (curricula) covering seven areas: Medication Management, Symptom Management, Recreation for Leisure, basic Conversation Skills, Substance Abuse Management, Workplace Fundamentals, and Community Reentry (skills for the transition from inpatient to outpatient environments).

In addition to its role as a stand-alone treatment, SST has also been combined with other interventions to address clinical problems in which social skills deficits are only one component. For example, several studies have combined SST with supported employment to improve workplace interactions and enhance vocational outcomes (Liberman et al. 2006, Wallace and Tauber 2004). Bellack et al. (2006) employed social skills training to teach drug abusing clients how to refuse drugs as part of a comprehensive substance abuse program. The specific contribution of skills training in these approaches has generally not been experimentally teased out, but it is widely assumed to be effective when the treatment package has proved to be successful. However, the one critical question that has not been clearly answered either in specific social skills training programs or when it is bundled into other treatments is the extent to which learning in the clinic translates into either specific behavioral changes or generally improved role functioning in the community.

There is scant evidence that there is spontaneous generalization from office based training to the community, which is not surprising given the well established behavioral aphorism that generalization must be programmed, not expected. That is, treatment must bridge the gap between office based training and the community by systematically prompting and reinforcing desired behavior and/or by engaging significant others in the community to do so. Liberman et al. (2001) have addressed this problem with a creative strategy referred to as in vivo Amplified Skills Training (IVAST). It combines standard skills training with intensive case management, based on the Assertive Community Treatment (ACT) model (Stein and Test 1985). The case manager helps support completion of homework assignments, identifies and reinforces opportunities to use trained skills, and establishes links with support systems (e.g., significant others) in the community to reinforce use of newly learned skills. Glynn et al. (2002) reported that IVAST was more effective than an office-based version of SST.

**Empirical Support**

The basic social skills training strategy was refined and validated in a number of single case studies and small group designs conducted in the 1970s and 1980s. These early reports were followed by a series of randomized clinical trials that has provided a clearer picture of areas in which SST is and is not effective. There have been at least 10 narrative reviews and four meta-analyses published in peer reviewed (English language) journals since 1990, including six published since the year 2000. Pilling et al. (2002) review of nine randomized trials was the most negative, and concluded that SST was not substantially effective. In contrast, the other reviews were all positive, and support the following conclusions (e.g., Bellack 2004, Kopelowicz et al. 2006).

1. SST is not highly effective for reducing symptoms or preventing relapse. This finding is not surprising. The only reason why SST might be expected to affect these domains is indirectly, by teaching skills that help to reduce social failure that could cause sufficient stress to precipitate exacerbations. This stress diathesis model depends on several mediating factors which are themselves unproven (e.g., that social failure produces sufficient stress to precipitate relapse).
2. SST has a reliable and significant effect on behavioral skills.
3. SST has a positive impact on social role functioning, although the findings here are not entirely consistent.
The results are better for defined skills, such as medication management or HIV prevention skills, than for general measures of social functioning.

4. SST appears to have a positive effect on satisfaction and self-efficacy: participants report feeling more self-confident in (targeted) social situations after training. SST is clearly an effective teaching technology that is well-received by both participants and clinicians.

These general findings are reflected in the following recommendation from the 2003 update of the Schizophrenia PORT (Lehman et al. 2004a)

*Persons with schizophrenia who have skill deficits such as problems with social skills or activities of daily living should be offered skills training. The key elements of this intervention include behaviorally based instructions, modeling, corrective feedback, and contingent social reinforcement. Clinic-based skills training should be supplemented with practice and training in the individual’s day-to-day environment (p 203).*

**Cognitive Rehabilitation**

Recognition of the importance of neurocognitive deficits has stimulated increasing interest in the prospects for cognitive remediation. It is difficult to trace the history of interest in this approach, but it certainly goes back at least as far as the early 1970s (Meichenbaum and Cameron 1973, Platt and Spivack 1972). However, these somewhat anomalous studies were not replicated and interest in cognitive training languished. Two reports in the late 1980s rekindled interest in the possibility of cognitive rehabilitation. Hans Brenner and colleagues (1990) developed a multistage approach, integrated psychological therapy (IPT), that attempted to marry cognitive training with higher level social skills training. Results have not been particularly robust but the work has had tremendous heuristic value.

The second study that had a significant impact was influential for very different reasons. Goldberg and colleagues (1987) reported that people with schizophrenia were unable to benefit from explicit instructions and practice on the WCST. Coupled with data demonstrating diminished blood flow while responding to the WCST, these data implied that schizophrenia was marked by an unmodifiable abnormality of the dorsolateral prefrontal cortex. The NIH (National Institutes of Health) work stimulated a series of mostly successful demonstrations that WCST performance deficits, albeit widespread, are neither endemic to the illness nor immutable (Bellack et al. 1990a, 1990b, Nisbet et al. 1996, Vollena et al. 1995). Other studies employed cognitive remediation strategies to improve performance on other measures of information processing as well. For example, Wexler and colleagues (1997) provided subjects with extensive practice on a motor dexterity task and either a visual reading task or a dot spatial memory task. Improved performance was gradually shaped over 10 weeks. A majority of subjects reached normative levels on the reading and dot tasks, and most showed improvement on the dexterity task as well. These results are consistent with other studies demonstrating that modest improvements can be observed on a variety of tasks using practice, shaping, and errorless learning (Silverstein et al. 2001). Stimulated by this early laboratory work, the last decade has seen a spate of clinical trials built around a series of innovative, clinically sophisticated strategies.

Several clinical programs are illustrative of the directions the field is pursuing. Wykes and colleagues (1999) developed an intervention called *cognitive remediation therapy (CRT)*, that focuses on executive functioning (e.g., cognitive flexibility, working memory, and planning). The approach employs a sophisticated training model that is based on principles of errorless learning, targeted reinforcement, and guided practice on cognitive tasks. Training media consist of a variety of paper and pencil games and neurocognitive tests. This group has conducted a series of trials that have yielded positive results for CRT, including some evidence of stability of effects over time (Reeder et al. 2006, Wykes et al. 2003, including some evidence of stability of effects over time (Reeder et al. 2006, Wykes et al. 2003). A limitation of this program is that it employs a highly tailored individual treatment model and demands high levels of therapist skill to slowly shape behavior. However, the focus on executive functioning seems much more likely to lead to transferable effects than narrowly focused programs designed to strengthen working memory or attention.

An alternative approach capitalizes on the ease of standardization and flexibility provided by computer software. Wexler and colleagues (1997) and Bell and colleagues (2001, 2004) reported positive results for similar programs that provide self-directed practice on basic attention, memory, and reasoning tasks (e.g., visual tracking, pyramids). Notably, the intervention had a positive impact on work outcomes, and the effects were maintained over time (Bell et al. 2004). These programs are limited in that the tasks are repetitive and boring for many participants, and they do not receive training per se. Participants may become more skilled on the specific tasks, but they do not necessarily learn effective strategies that normalize dysfunctional neural circuitry or foster generalization to other situations.

Medalia (Medalia and Revheim 1999, Medalia et al. 2000) developed an innovative program called *Neuropsychological Educational Approach to Remediation (NEAR)* that employs commercially available educational software. These tasks are intrinsically interesting to subjects and have built-in feedback mechanisms to guide performance. The intervention is administered in an open classroom format in which people attend on an *ad lib* basis, select tasks they are interested in working on each day, and move at their own pace. Medalia emphasizes self-directed practice, rather than structured training, in order to foster “intrinsic motivation” for learning and to allow people to enhance their preferred problem-solving styles. This is an appealing approach, but reliance on self-directed practice seems unlikely to lead to learning. Neuroimaging data suggest that individuals use inefficient neurocognitive operations and are unable to utilize appropriate (i.e., normal) neural circuits to perform cognitive tasks (Frith 1995, Weinberger et al. 1992). Consequently, practice without training may improve performance on the specific task practiced but it is not likely to normalize functioning or lead to transferable gains.

Bellack and colleagues (2005) have developed a remediation strategy that is built around educational software developed for children: *Computer Assisted Cognitive Remediation (CACR)*. CACR was guided by four premises about cognitive impairment and the rehabilitation needs of people with schizophrenia.
1. Remediation should target controlled and coordinated cognitive activity, rather than individual neurocognitive domains. Thinking problems in schizophrenia arise out of abnormalities in the coordinated activity of many brain regions that subserve a wide range of integrated neurocognitive abilities; thus, a focus on any specific neurocognitive domain is premature and remediation must target this coordinated activity.

2. Remediation should thoughtfully integrate training and independent practice. Prior investigations have shown that strategy training, on the one hand, and repetitive, independent practice, on the other, can improve neurocognitive performance. Strategy training likely addresses deficits in the strategic, “top–down” cognitive control and coordination of mental activity. Independent, repetitive practice may better target the more discrete “bottom-up” processes and may build up speed and capacity for mental effort. These appear to be separate and complementary pathways to beneficial cognitive change and remediation must coordinate and integrate their use.

3. Bearing in mind the goal of standardization, remediation should be individualized, to the extent possible. Given the variability in the severity and distribution of cognitive deficits, in compensatory adaptations, and in learning styles and preferences, remediation must also provide enough flexibility to accommodate substantial individual differences.

4. Remediation must take account of motivational emotional deficits. Motivational and emotional processes are part of the foundation for cognitive performance. Given that negative symptoms and motivational impairment are core features of schizophrenia, it is essential that a remediation program build in strategies to secure engagement and sustained, active participation in remediation procedures.

CACR employs six commercially developed educational software tasks. Three specifically target planning, reasoning and problem solving skills, while also tapping attention, memory, and other capacities. Two place a premium on the use of attention, working memory and learning. The last is a speeded task that emphasizes rapid perceptual integration, decision making and response.

The graduated nature of the CACR exercises ensures that most clients will face impasses at multiple points, giving rise to numerous discrete opportunities for active intervention by trainers. The structure trainers provide in these instances comes under the rubric of scaffolding in the learning literature and also draws on principles of errorless learning. A scaffolding approach implies a division of current task responsibilities between the client and trainer. The client manages those parts of the task within his or her ability (e.g., the individual actions within a sequence). The trainer provides the complementary skills to enable successful performance (e.g., the larger strategy and goal orientation). Trainers shape and monitor individual strategies and actions, model more global problem solving processes, and provide gentle pressure to try more difficult task levels as client performance improves. The flexible support provided by trainers prevents preservative use of unproductive strategies, allows clients to progress while keeping errors to a minimum, and counteracts client frustration with positive reinforcement. The trainer gradually relinquishes strategic control as the client increases competence.

Preliminary data from two randomized clinical trials of CACR are quite promising. Subjects clearly improve in performance on each of the training tasks and report very positive subjective experience of the intervention. Further work is required to determine whether the effects translate into improved community functioning.

Judging the potential for cognitive rehabilitation based on existing trials (analog or clinical) is difficult due to the risk of Type II error (e.g., incorrectly concluding that it is ineffective). It may be safe to conclude that a particular strategy is not effective, but one cannot extrapolate from any single trial or group of trials to the broader domain. For example, a particular technique that fails to produce an effect in 10 training sessions might be effective after 50. Ten sessions of practice on computerized memory tasks may not be sufficient to produce a generalizable increase in processing capacity, but meaningful changes may become apparent after 100 sessions. Alternatively, an innovative program based on a different conceptual model could produce results that the simpler practice/rehearsal strategies currently in vogue do not. The literature is also difficult to evaluate given the broad diversity of training procedures, subject samples, and outcome measures employed in trials.

Several reviews have concluded that cognitive remediation can be effective and merits the designation as an evidence-based practice (e.g., Twamley et al. 2003a, Velligan et al. 2006). Conversely, Pilling et al. (2002) were quite critical, based on data collected at the time of their review. At the least, the evidence suggest that cognitive remediation is a promising avenue to pursue, having demonstrated the ability to produce statistically significant changes in neurocognition that are sustained over time in several studies. There is also evidence that remediation programs can produce meaningful changes in community behavior, including social functioning and work (Bell et al. 2004, Reeder et al. 2006). However, there is not yet strong evidence to support the widespread dissemination of any particular approach as a cost-efficient, evidence-based practice, and cognitive remediation was not identified as an evidence-based practice in the most recent Schizophrenia PORT update (Lehman et al. 2004a). Further, it remains unclear which aspects of neurocognition are critical targets for training, or which are most likely to be malleable (Bellack et al. 2005, Reeder et al. 2006). This is a significant problem for the field and is retarding progress in developing truly effective intervention strategies.

**Vocational Rehabilitation**

The ability to perform productive work, earn money, and achieve a degree of independence is generally regarded as a major factor in self-esteem, quality of life, and relationships with significant others. Yet it is a domain that is particularly difficult for people with schizophrenia. Rates of competitive employment for persons with the illness are generally less than 25%, and participation in sheltered employment is not much better (Lehman 1995). Nonetheless, many, if not most people with schizophrenia express the desire to work, especially in competitive jobs (Cook et al. 2005a).

There are many forms of vocational programs available in the community, including sheltered workshops, job clubs,
transitional employment, the Boston University model, and programs of job support. With the exception of programs involving job support, there is little evidence that these types of vocational interventions often result in sustained competitive employment among patients with severe mental illness (Lehman 1995). Rather, such programs appear to provide many individuals with structured opportunities for socialization and individuals, it is clear that traditional approaches to psychiatric rehabilitation have proven to be disappointingly ineffective for those interested in competitive employment. In part, this lack of efficacy may be attributed to residual symptoms and the severe disability that is common among people with schizophrenia. Further, the negative financial incentives that have traditionally been built into the Supplemental Security Income (SSI) and Social Security Disability Income (SSDI) systems may have played an important role in people choosing long-term involvement with rehabilitation programs rather than actual competitive employment. Thus, there are both illness and systems factors that may contribute to the limited efficacy of traditional rehabilitation approaches. Even allowing for these factors, it is clear that improvement of vocational functioning among people with severe mental illness remains a critical goal for psychosocial intervention.

Optimism about the potential to increase rates of employment has increased since the mid 1990s with the development of supported employment, an innovative strategy that provides support in the community to help people find and keep competitive jobs, rather than assigning them to an extended period of vocational training. The most widely studied and disseminated model of supported employment, Individual Placement and Support (IPS) was developed and standardized by Robert Drake and Deborah Becker (Becker and Drake, 1993, 2003). It is based on six principles (Bond 2004): (1) services are focused on competitive employment; (2) eligibility is based on consumer choice, not screening criteria or counselor determined readiness; (3) the focus is on rapid job search, rather than a preliminary period of training or rehabilitation; (4) the program involves active integration of mental health and vocational services, rather than a balkanized or brokered model; (5) services are based on consumer preferences and choices rather than professional judgments of what the person can/should do; (6) The program is not time-limited: vocational staff provide follow-along support for as long as needed to help the person succeed on the job and/or find successive jobs if the person does not like or cannot retain the first (or second, etc.) position.

There is a growing body of literature documenting the efficacy of supported employment (Bond 2004, Twamley et al. 2003b). Studies have been conducted in diverse geographic regions in the US and Europe, with heterogeneous client groups. Summarizing the results of nine randomized trials completed at the time of his review, Bond (2004) reported that competitive employment rates for subjects in supported employment averages 56%, compared to 19% for those in traditional vocational rehabilitation programs. Cook and colleagues (2005a,b) conducted a multi-site trial in which 1273 outpatients recruited from seven (US) states were randomly assigned to supported employment or control conditions for 24 months. Fifty-five percent of those in supported employment had achieved competitive employment for at least part of the time, versus 34% of those in the control condition. Those in supported employment also had significantly higher earnings and were significantly more likely to be working for 40 hours or more per month.

While the results for supported employment are, thus, quite promising, it should be noted that it is not a cure for unemployment among people with severe mental illness. The majority of clients are employed at minimum or close to minimum wages, albeit in competitive employment. Few are able to work full time (i.e., 35—40 hours per week), and many are unable to retain jobs for long periods of time. Conversely, many who lose jobs are able to find subsequent employment and there is some suggestion that stability of employment increases over time (Bond 2004). Much attention in the literature is now being placed on strategies to increase employment success through the use of adjunctive treatments, such as cognitive remediation (McGurk et al. 2005) or social skills training (Wallace and Tauber 2004).

Overall, despite the limitations in its effects, the evidence base for supported employment is very strong and it is widely regarded as an evidence-based practice. It is one of the 6 psychosocial strategies recommended by the Schizophrenia PORT (Lehman et al. 2004a): Persons with schizophrenia should be offered supported employment, the key elements of which include individualized job development, rapid placement emphasizing competitive employment, ongoing job support, and integration of vocational and mental health services (p 202).

Summary and Conclusions

This chapter has provided an overview of issues involved in providing effective rehabilitation programming for people with schizophrenia. Interest in psychosocial treatment, including rehabilitation has waxed and waned over the last several decades, but there is now widespread agreement that it plays a critical role in comprehensive care for people with the illness. Schizophrenia is the result of a failure in normal neurodevelopment, with subtle manifestations evident long before the first exacerbation. There appears to be a lifelong disruption of normal socialization coupled with enduring neurocognitive impairments that make it unlikely that medication alone can be sufficient to produce adequate quality of life. That being said, several factors were discussed that must be addressed if psychosocial treatments are to be effective, including: (1) timing and duration of treatment; (2) individual differences in treatment needs; (3) the role of the person in treatment; (4) the limitations imposed by impairments in information processing; and (5) the need to base interventions on a compensatory model.

Three rehabilitation strategies that have received considerable attention were then reviewed: social skills training (SST), cognitive rehabilitation, and vocational rehabilitation. SST is an effective teaching/training strategy but it is not clear that the intervention can produce meaningful changes in community performance unless it is embedded in a comprehensive, community oriented intervention program. The potential for cognitive rehabilitation is less clear. Several approaches seem to be based on an overly simplistic model of neurocognitive functioning and place too much reliance on an exercise model that attempts to alter brain function by repeated practice. Newer strategies that focus on improving higher level integrative processes may prove

Chapter 96 • Psychosocial Rehabilitation
to be more effective, especially those that employ computerized educational software that clients find inherently engaging. Traditional vocational training that emphasizes sheltered workshops and job training have not been highly effective. The integrated placement and support model is an innovative new approach that helps place clients in competitive employment and provides ongoing support in the real workplace. Initial results are very promising, although job retention and total hours clients are able to work remain problematic.

As evidenced by these three approaches, the scientific literature is moving away from long-term, unfocused day treatment approaches to targeted intervention strategies designed to deal with specific problems. This approach, which is much more likely to produce useful outcomes has not yet had adequate penetration of community services. Further research is required to match interventions with individuals to determine when specific interventions should be provided, and to build in sufficient booster or follow-up procedures to maximize the chances for enduring change in the community. It is by now very apparent that neither a one-size-fits-all nor a time-limited, up-and-out approach works with this population.

Cook JA, Leff S, Blyler CR, et al. (2005a) Results of a multisite randomized trial of supported employment interventions for individuals with severe mental illness. Archives of General Psychiatry 62, 505–512.

Psychiatry now recognizes the critical need to integrate psychopharmacological treatments with psychotherapeutic supports and services for adults with a severe psychiatric disorder to achieve an optimal level of social and role function, a reduction in relapses, and a satisfactory quality of life. Since psychiatric medications only target the positive symptoms of these disorders, they do not address the functional disabilities that often result from the illness (Keefe et al. 1999). Psychiatric treatments are focused on controlling symptoms of severe mental illness, while the intended purpose of the psychosocial interventions described in this chapter are to ameliorate the associated functional loss of these illnesses or the consequent disability. Hence, without this combination of interventions, many adults with a severe psychiatric illness would not improve in the realm of the psychosocial sequelae of these disorders, and consequently, not be able to achieve successful community living.

Currently, there is a diversity of effective psychotherapeutic programs and services specifically designed to meet the needs of adults with psychiatric disabilities. This chapter will focus on the psychotherapeutic half of the equation, with specific emphasis on those interventions that are considered to be evidence-based practices (EBPs). The chapter will begin by defining the population of those with psychiatric disabilities, followed by a discussion of psychiatric rehabilitation, including what it is, the history of its emergence and development, its principles, and specific practice approaches. Next, a presentation of the recovery orientation will be provided with an examination of its relevance to the provision of these service interventions. Finally, an in-depth discussion of each of the five accepted psychotherapeutic EBPs will be presented, placing each within the context of related services and providing a summary of the empirical evidence.

**Defining Adults with Psychiatric Disabilities**

Adults with psychiatric disabilities are individuals who, as a result of their mental disorder, are unable to achieve commonly accepted age-appropriate milestones in major life domains, such as participating in educational programs, employment, or engaging in social commitments, including intimate relationships and marriage. An important aspect of this definition is that psychiatric disability is based on a diagnosable mental illness. The diagnoses that frequently result in psychiatric disability are those considered to be the severe mental illnesses, which include the schizophrenia spectrum disorders and the major affective disorders, major depression, and bipolar disorders. In some cases, individuals with anxiety and personality disorders are also included, but the former diagnoses are characteristic of the
majority of the population. It is important to note that not everyone with these disorders has a psychiatric disability. Only those in which the symptoms of the disorder interfere with the individual's ability to pursue their life goals, which are socially and culturally appropriate for their given physical developmental state, are considered disabled. However, the US National Health Interview Survey found that 79% of over 3 million adults with severe mental illness have at least one functional limitation (Barker et al. 1992 as cited in Bassett et al. 1998). Sanderson and Andrews (2002) caution that assessing disability just for those with severe psychiatric disorders underestimates the prevalence of disability, as those with affective, panic, posttraumatic stress, and generalized anxiety disorders were the most prominent diagnostic categories with the highest levels of disability in their Australian National Survey of Mental Health and Wellbeing. Overall, this household survey determined that 68% of adults with any mental disorder had anywhere from a mild to a severe disability, but only 23% of those without a mental disorder were assessed to have a disability, with most being mild.

There is a wide diversity of definitions of disability for both research and services purposes. For example, definitions of disability vary by benefit programs, such as the Social Security Administration, Rehabilitation Services Administration, and Substance Abuse and Mental Health Services Administration (SAMHSA), as these definitions determine eligibility for the provision of services and resources, including financial support in the case of Supplemental Security Income or Social Security Disability Income. Despite this diversity, all definitions appear to share some basic principles. Those with disabilities are considered to suffer from an illness, i.e., a disease or disorder; experience signs and symptoms of the disorder that are significant enough to cause impairments, i.e., loss of physical or mental functions; and also experience a loss of ability or competence in social role functions (see Table 97–1 for examples of definitions of disability by federal agencies).

<td>Disability is based on the inability to work. An individual is considered disabled under Social Security rules if the individual cannot do work that he/she did before, and it is decided that the individual cannot adjust to other work because of medical condition(s). The disability must also last or be expected to last for at least one year or to result in death.</td>
</tr>
</tbody>
</table>

An investigation by the World Health Organization (WHO) determined that mental illnesses are the leading cause of disability worldwide. The WHO study determined that the severe mental illnesses, schizophrenia, depression, and bipolar disorders, accounted for almost one quarter of all disability in the industrialized countries (WHO 2001). The Global Burden of Disease Study by WHO, which calculated disease burden by disability adjusted life years (DALYs), enabled a comparison across a diversity of diseases. DALYs estimate the lost years of healthy life, regardless of whether the years are lost to premature death or years lived with a disability. The disability component of the DALY measure is weighted for disability severity. Based on this calculation, major depression was ranked in the top 10 priority diseases and was second only to ischemic heart disease with regard to the burden of disease (Utsun 1999). Furthermore, mental disorders accounted for almost 10% of the burden of disease in established market economies (Utsun 1999). Consistent with these findings, Marcote and Wilcox-Gok (2001) estimated that in the US alone, 5–6 million people between the ages of 16 and 54 lose, do not seek, or are unable to secure employment due to the consequences of mental illness. They further estimated that those with mental illness who do work have their annual incomes reduced anywhere from $3,500 to $6,000. Based on an examination of the US National Comorbidity Survey data, Kessler and Frank (1997) determined that work impairment was a primary adverse consequence of psychiatric disorders. They found that the average days of work lost due to psychiatric disorders was 6 per month per 100 workers, and an average of 31 days per 100 workers reduced their performance or productivity at work, and moreover, work disability was more highly concentrated among those with comorbid psychiatric disorders.

Prevalence Estimates Of Psychiatric Disability

US Public Law (PL) 102-321, the Alcohol, Drug Abuse, and Mental Health (ADAMHA) Reorganization Act of 1992 required the states to estimate the incidence and prevalence of adults with serious mental illness (SMI) in order to determine the allocation of block grant funds for community mental health services. This law defined serious mental illness as any diagnosis in the Diagnostic and Statistical Manual (DSM) other than a substance use disorder accompanied by a “serious impairment,” operationally defined as a Global Assessment of Functioning (GAF) score below 60.

SAMHSA, an agency created by the 1992 legislation, established a task force to develop a methodology for determining the estimates of those with SMI, based on two national surveys of DSM disorders in the United States: the Epidemiologic Catchment Area (ECA) study (Robins and Regier 1991) and the National Comorbidity Survey (NCS) (Kessler et al. 1994). Given that these studies were not designed to assess impairment, imprecise indicators were used. The task force “estimated that 5.4 percent of the US noninstitutionalized civilian population met [sic] criteria for SMI at some time each year” (Kessler et al. 2002, p 156). More specifically, these authors noted that “[p]reliminary prevalence estimates based either on post hoc secondary analysis of previously collected psychiatric epidemiological surveys or on indirect estimates from screening scales suggest that 2.4 to 3.3 percent of the US adult population meet criteria for SMI in any given month and that 5.4 to 7.2 percent do so at some time during the year” (p 163).
Bassett and colleagues (1998) estimated the prevalence of disability by utilizing various measures of disability that were applied to data from Eastern Baltimore Mental Health Survey, an ECA site. The proportion of adults with a disability (functional limitation) varied between 2.5 and 19.5% contingent on which measure was employed. The low rate was produced with a score of 5 or greater on Axis V of social and occupational functioning of the DSM, while the highest was produced when the presence of two or more chronic medical conditions was used. Overall estimation of the prevalence of being disabled by at least one of the indicators employed was 39.5%. Of adults classified as being disabled by any of the measures examined, 56–92% had a psychiatric disorder.

**Defining Psychiatric Rehabilitation**

Characteristically, adults with severe psychiatric disabilities are generally unemployed, unmarried, and have difficulty with interpersonal relationships. Given their lack of employment, they are often financially supported through federal disability programs or have intermittent employment or limited family financial support. Consequently, this population tends to be economically disadvantaged and to be vulnerable to a diversity of societal ills, including relatively high rates of substance abuse, psychological trauma, homelessness, criminal justice involvement, and loss of custody of their children. They also have a number of cognitive deficits and medical comorbidities as well as high rates of suicide.

Given the functional limitations of the population, a diversity of psychotherapeutic practices, programs, and services within the domain of psychiatric rehabilitation have been developed to meet the population’s multiplicity of needs. A commonly accepted definition of psychiatric rehabilitation is assistance to adults with psychiatric disabilities in increasing their ability to function effectively with life satisfaction in the environments of their own choosing with the least amount of continuing intervention by professionals (Anthony et al. 2002). The emphasis of psychiatric rehabilitation is on consumers acquiring the necessary skills and resources for living in the community as independently as they desire and are capable. The primary practice goal is “to enable individuals to compensate for or eliminate the functional deficits, interpersonal barriers and environmental barriers created by the disability, and to restore ability for independent living, socialization, and effective life management” (Hughes 1994, p 11). The primary practice domains of psychiatric rehabilitation include independent living, education and employment, personal relationships, health, criminal justice, and spiritual life and recreation, thereby encompassing all aspects of social functioning and community living. Psychiatric rehabilitation employs systematic practice efforts that assist adults with psychiatric disabilities to progress in their own course of recovery (Corrigan et al., in press). Psychiatric rehabilitation practice differs from psychiatric treatment, which is comprised of psychiatric medication administration and management and psychotherapy. It is important to note that intensive insight-oriented psychotherapy is not commonly utilized for adults with psychiatric disabilities as it has been empirically determined that these interventions tend to have negative consequences for those with schizophrenia disorders (Drake and Sederer 1986). However, supportive psychotherapies have been shown to be effective with this population, as have some cognitive behavioral treatments.

Although the identification of the practice of psychiatric rehabilitation began in the 1940s, psychiatric rehabilitation has become designated as a field of practice much more recently. Psychiatric rehabilitation is the integration of a multiplicity of program approaches and models that were all designed to treat the psychosocial conditions and functional limitations of adults with psychiatric disabilities. This is the single professional practice field that is limited to working with only one very specific population. Psychiatric rehabilitation is more than specific practices. It is also comprised of principles and values that guide rehabilitation practices.

**Development of Psychiatric Rehabilitation**

The roots of the field go back to the 18th century with the introduction of moral treatment, where patients were to be treated with respect and kindness, and relocated to the rural pastoral areas where it was believed that the setting would restore prior functioning (Corrigan et al. in press, Morrissey and Goldman 1984). The emergence of the principles of psychiatric rehabilitation goes back even further, to the provision of normalized housing for those who made pilgrimages to the village of Geel Belgium in the 13th century in search of a cure for their mental illness. Town folks took in pilgrims with mental illness to live in their homes on a permanent basis. In the US, Dorothea Dix crusaded for the establishment of mental hospitals in order to offer more humane treatment, rather than having adults with mental illness living in almshouses, jails, or on the streets. The US mental hygiene movement of the 19th century was a reaction to the poor quality of care for those served in public psychiatric institutions. In the 20th century, the deinstitutionalization movement was a major precipitant to the further development of psychiatric rehabilitation practices by treating those with SMI in their community rather than warehousing them in large institutions. With the recognition of the inadequacies of the community mental health movement of the 1960s in meeting the psychosocial needs of adults with SMI, the National Institute of Mental Health (NIMH) developed the Community Support Program (CSP). CSP promoted an approach of an entire system of care that was ongoing, rather than episodic or crisis oriented. The principles of CSP were very much influenced by psychiatric rehabilitation movement leaders. Consequently, the values and beliefs of the field were evident in the articulation of these CSP principles (Corrigan et al. in press). The philosophy of CSP was embodied in a set of principles, which included services being consumer centered, empowering, culturally and racially appropriate, flexible to meeting consumer needs, focused on consumer strengths, normalized with inclusion of natural supports, accountable to consumers, families, and administrators, and coordinated with a system of care (Stroul 1993). CSP promoted the dissemination of programs and approaches of psychiatric rehabilitation, which helped to promulgate and further the development of the field.

Psychiatric rehabilitation has now achieved legitimacy as a field of practice. For a number of years, the Commission on Accreditation of Rehabilitation Facilities (CARF) has accredited vocational rehabilitation services in behavioral health care, and they now also accredit programs such as
Assertive Community Treatment (ACT). Psychiatric rehabilitation practitioners have recently obtained certification. Many of the practices have a research base, with some of them considered to be EBP. A number of books that define the field and explicate the principles, practices, approaches, as well as service models have been and are being published (e.g., Corrigan et al. in press, Pratt et al. 2006). Furthermore, there is at least one academic department that is totally dedicated to the teaching of psychiatric rehabilitation and that grants all levels of postsecondary degrees, the Psychiatric Rehabilitation Department at the University of Medicine and Dentistry of New Jersey, while other departments or schools like psychology programs and schools of rehabilitation have a specialization in psychiatric rehabilitation.

**Principles and Service Elements of Psychiatric Rehabilitation**

The emphasis in psychiatric rehabilitation is on the strengths of the individual, rather than on their deficits. Implicit in the strengths perspective is the empowerment of the person. Furthermore, there is a belief in the self-determination of the individual with attention given to personal goals and preferences. Consequently, a key element of psychiatric rehabilitation is the active involvement of the consumer in the development, implementation, and ongoing evaluation of service plans and recovery process. Consistent with the orientation of psychiatric rehabilitation is the centrality of hope, optimistic activist philosophy, and a belief in the consumer's own recovery to gain control and acceptance of their life and their illness, despite their disability.

Given the nature of mental illness and its resulting disability in many functional areas, psychiatric rehabilitation takes a comprehensive approach focusing on practical concerns with daily living and integration with psychiatric treatment, specifically pharmacotherapy. A key principle is that services need to be normalizing, offering experiences that are not different from those without disabilities. Rehabilitation emphasizes the teaching of skills, as well as the modification of environments and the provision of environmental supports with the goal of maximizing the likelihood that the individual will succeed in the environment of choice. Rehabilitation is not a one-time intervention, but rather an ongoing process. Rehabilitation is best performed when it is situationally based in the consumer's own environment. Services are most beneficial when integrated in the community, the locus of the training. This approach is based on experiences that the more the services are delivered in the consumer's own environment, the more likely that the acquired skills will be used in that setting. The rehabilitation process is more effective with the inclusion of family members and other natural supports of the consumer's own choosing (Kopelowicz et al. 2006).

**Examples of Psychiatric Rehabilitation Practices**

Psychiatric rehabilitation is an amalgamation of a diversity of practice approaches. Four primary practice approaches, with each promoting the rehabilitation of adults with SMI and each developing rather independently of the other, have merged together to form the foundation of what is now considered the field of psychiatric rehabilitation: psychosocial rehabilitation centers, specifically the clubhouse model (Rutman 1987); social skill training (Bellak 2004); Boston University approach, particularly the choose, get, keep model (Anthony et al. 1987); and peer support approaches developed and delivered by consumers (Solomon 2004, Solomon and Draine 2001).

**Psychosocial Rehabilitation Center Movement and the Clubhouse Model**

One of the primary impetuses in the development of the field was the psychosocial rehabilitation center movement, which started with the establishment of Fountain House in New York City in 1948. A group of discharged psychiatric patients formed a self-help organization, We Are Not Alone Society. This self-help group, with assistance from volunteers and funded by a charitable foundation, eventually evolved into a community-based program known as Fountain House. This organization was frequently referred to as a psychosocial “center”; hence, with the development of other similar programs across the country, these agencies became the psychosocial center movement. The particular program model came to be identified as the Clubhouse model, as this was a central meeting place for members to socialize. There are now over 300 clubhouses in 24 countries worldwide. Individuals who participate in these programs are called “members,” rather than patients or clients, so as to communicate an atmosphere of support, acceptance, and respectfulness. The services are offered in a nonstigmatizing environment and in an atmosphere that maximizes the members’ “feeling of responsibility and self-worth and encourages ownership in the rehabilitation process” (Rutman 1987, p. 204). These centers provide opportunities for work, socialization, and, in some cases, housing (Rutman 1993). These programs have a number of groups that meet on an ongoing basis to offer skills and support to other members. Members participate in the operation of the organization by holding functional jobs in the program. A central feature is the work ordered day; thus, members work as receptionists, perform janitorial or housekeeping services, prepare the noon day meal, and maintain fiscal and clinical records. The service programs are aimed at improving educational, vocational, and independent living and socialization skills of the members. Today, a number of comprehensive community mental health agencies have added clubhouse programs as a component of their array of services.

The clubhouse model of psychiatric rehabilitation is a place where individuals with a mental illness “come to rebuild their lives.” Members are free to choose the frequency and intensity of contact with the clubhouse, including its staff, other members, and program elements. The focus is on members’ strengths. Fellow members reaching out to other members is the core healing process, and members work with staff in partnership, sharing roles and responsibilities. Staff do not function as therapists. One of the program features of clubhouses is transitional employment (TE). TE is the placement of a member in a time-limited, usually 6 months, job in the community where the employee receives the prevailing wage. The clubhouse guarantees that the job will be performed, with staff filling in should the member be unable to attend. However, these are not permanent jobs, but rather the agency “owns” the position, and every 6 months places another member in the same position. These job placements are a step toward increased independence.
In 1994, the International Center for Clubhouse Development (ICCD) was formed to help and to represent this growing movement worldwide. ICCD was established to provide training in the model, offer consultation to developing programs, and to certify that operating clubhouses meet the standards of a clubhouse to ensure that the integrity of the model is maintained (Macias et al. 1999). Unfortunately, there has been limited research to determine the effectiveness of this model.

Social Skills Training
A more highly structured approach to the practice of rehabilitation of adults with psychiatric disabilities is social skills training. Social skills training is systematic strategies and techniques to teach interpersonal skills that are based in social learning theory. The general approach of highly structured curriculums that employ systematic behavioral techniques has virtually remained unchanged since its inception in the 1970s (Bellack 2004). An underlying principle of skills training is that essentially all social behaviors are learnable (Bellack 2004). The settings in which these trainings occur is wide ranging, from hospitals and community-based service settings to the actual locations in which the skills that are being taught will be used. A number of social skill programs started in hospitals. For example, some were token economies, where patients were given tokens that could be exchanged for goods, e.g., candy and cigarettes, for engaging in positive behaviors. Given the cognitive limitations of the population, evidence indicates that teaching skills \textit{in vivo} is more effective than in service arenas that require subsequent generalization of the acquired knowledge to other settings and situations (Corrigan et al. in press).

Skill trainers are essentially teachers as opposed to therapists (Bellack 2001). These trainers employ principles and techniques of behavior therapy for teaching social skills (Kopelowicz et al. 2006). Social skills training entails consumers learning specific interpersonal skills and personal competencies through methods that promote the maintenance and generalization of new or rehabilitated skills to increase social competencies, social role functioning, and quality of social relationships (Bellack 2001, Mueser et al. 1997). Initially, much of the training focused solely on behavioral skills, but now includes social, perceptual, and cognitive skills as well (Mueser et al. 1997). Given the grounding of the approach in social learning theories, social skills training is conducted with highly structured educational procedures, in contrast to less-specific resocialization experiences. Group social experiences, such as attending an organized social activity at a psychosocial center, provide opportunities to practice interpersonal skills, receive consensual validation for acceptable behaviors, and obtain positive as well as negative feedback. However, these responses depend on the chance occurrence of the nature of attendees and events, rather than on prepackaged or systematically prescribed training experiences.

The resocialization experiences offered in psychosocial clubhouses are different from social skills training. In contrast to informal resocialization experiences, the highly systematized programs of social skills training employ specific behavioral techniques such as role playing, social modeling, positive and corrective feedback regarding appropriate behaviors, coaching, didactic instructions, attention-focusing procedures, problem-solving techniques, and homework assignments. Once deciding on the targeted behavior to be taught, complex behaviors are broken down into discrete behavioral elements, and the individual is trained for each element employing various techniques. Once the individual can perform the elements, then gradually the elements are taught to be combined. Skills are frequently taught in groups with two trainers, one directs sessions and the other role plays. Teaching a circumscribed skill usually takes 4–8 sessions, while a more comprehensive skill may take anywhere from 6 months to 2 years. Training sessions frequently occur 2–3 times per week (Bellack 2004). Sessions can also be conducted on an individual basis or with family members or other social network members, as these individuals can help to encourage and reinforce the use of the skill (Kopelowicz et al. 2006).

Robert Liberman, and his colleagues at the Center for Research on Treatment and Rehabilitation of Psychosis have developed a number of skill training modules that have been widely disseminated and are available for purchase (http://www.mentalhealth.ucla.edu/). These modules include medication management, symptom management, recreation for leisure, community reentry, job seeking, and workplace fundamentals training. The modules contain a videotape of a role play demonstration, a trainer’s manual, and a patient workbook. The center also has a number of clinical manuals available, such as management of aggressive behavior, and involving families in mental health services for adults with SMI.

The patient outcomes research team (PORT) on schizophrenia has recommended social skills training (Lehman et al. 2004). Research has demonstrated the efficacy of the approach for teaching a range of behaviors, including conversational skills, assertiveness, heterosocial skills, and medication management. However, many of the studies have been conducted with those with schizophrenia and in inpatient settings (Dilk and Bond 1996). Bellack (2004) reviewed 12 meta-analytic and narrative reviews of social skills training and concluded that social skills training does not reduce or prevent relapse; but this psychotherapeutic approach does improve targeted behavioral skills; seems to have a positive impact on social role functioning, although results are inconsistent in this regard; and improves consumer’s sense of self-efficacy with targeted social situations after training. Furthermore, consumers and providers are highly satisfied with the technology. The approach is most effective when it is in embedded in a broad, comprehensive rehabilitation program (Kopelowicz et al. 2006). Recently, social skills training has been incorporated into community-based case management services in order to help to increase the transfer of skills to community settings. For example, enlisting family members, coworkers, and peers to provide feedback and cues in “real” situations has been demonstrated to be useful. Combining psychoeducation and skills training is effective in improving communication among family members and, consequently, reducing environmental stress. Skills training has been found to enhance cognitive functioning. However, to date, no studies of cognitive rehabilitation have demonstrated a clinically significant effect on community outcomes. Cognitive rehabilitation seems to have potential, but data demonstrating its effectiveness are not yet available (Bellack 2004). Wexler and Bell’s (2005) research on cognitive remediation...
treatment with work therapy and supported employment demonstrates clinically significant improvements in cognition as well as work functioning.

Although some attempts have been made to enhance social skills into the consumers’ own environment, questions remain as to the efficacy of this approach in terms of the transfer of learned behavioral skills by consumers to every day life settings and in terms of improved social functioning in daily routines by the use of such skills (Kopelowicz et al. 2006). Efforts to facilitate the transfer of skills from the training environment to the natural environment is essential, otherwise generalization may not occur. There has been a variety of recent attempts that “offer opportunities, encouragement, and reinforcement for using in the community those skills learned in training” (Kopelowicz et al. 2006). For example, In Vivo Amplified Skills Training (IVAST) involves specialized case managers who assist with the application of newly learned skills to the community setting. Research has found that those with this supplementary support have higher levels of interpersonal problem-solving skills, significantly improved social adjustment, and a better quality of life over a 2-year time frame than those who received only the skills training (Glynn et al. 2002). Kopelowicz et al. (2006) studied the use of indigenous or natural supports serving some of the functions of the case manager. In this approach, the consumer selects supporters based on criteria of cooperativeness, accessibility, and familiarity with the environmental setting. The selected supporters were provided brief training and weekly supervision by the case manager for their efforts on behalf of the consumer. Evaluation of this approach revealed that participants who received this support in addition to the skill training increased their interpersonal and community functioning during the 18-month follow-up period post-training; while those who only received the skill training lost some of their improvements during the course of the study (Tauber et al. 2000). A similar approach employed Latino family members to teach skills and enhance the application of these skills for their relatives with schizophrenia. Again, this approach demonstrated improvements, i.e., fewer hospitalizations compared to those receiving usual care (Kopelowicz et al. 2003). Thus, there is some promise in approaches that promote supplemental skills training to offer opportunities for application to daily life activities in the community.

**Boston University Rehabilitation Approach and the Choose-Get-Keep Model**

The Center for Psychiatric Rehabilitation at Boston University engages in research, training, and service provision to improve the lives of those with psychiatric disabilities. The Director of the center, William Anthony, who was educated in physical rehabilitation, has been very influential in the promotion of the practice and values of psychiatric rehabilitation. He was one of the first professionals to define, articulate, and promote the relevance of the concept of recovery for this population. This center has developed a specific rehabilitation approach.

The Boston University or BU approach consists of three phases: the diagnostic, planning, and intervention phases (Pratt et al. 1999, Anthony et al. 1987). This approach is based on the premise that successful rehabilitation processes begin with an assessment of the client’s readiness to engage in rehabilitation activities, the client’s current skills, and the environments in which the client operates. Based on this information, a plan which prioritizes goals and objectives is formulated in partnership with the client. Finally, strategies and interventions for accomplishing the goals and objectives are delineated (Pratt et al. 1999).

The client with the aid of a rehabilitation practitioner defines the rehabilitation goal(s) in a selected domain, such as socialization, housing, self-care, employment, or education that the client wishes to achieve in a reasonable period of time, often in 6–18 months. The diagnosis then involves a crucial step, i.e., a functional assessment, during which the client and the rehabilitation practitioner develop a list of the client’s assets or abilities, as well as handicaps or disabilities relevant to the achievement of the goal(s). The assessment proceeds to explore questions such as which skills does the client have and which additional skills does the client require to achieve the goal successfully, for example, in acquiring a job or date, living independently in an apartment, or succeeding in school (Anthony et al. 1987).

A third dimension of the assessment or diagnosis is an evaluation of the client’s environment and support system. The client’s environment is assessed as to whether it is conducive to the achievement of the client’s goals and the extent to which there are environmental barriers that may hinder their accomplishment. Thus, an assessment of both the client’s personal needs and environmental requirements is essential to a realistic psychiatric rehabilitation diagnosis (Anthony et al. 1987). For example, questions such as the following are posed with regard to obtaining and maintaining employment: Can the person handle a full-time job or is a part-time position a better fit? Can the person share a job? Is she or he best able to function with written rather than oral instructions?

Upon completion of the diagnostic assessment, the client and practitioner jointly determine priorities for skills development and environmental or resource modifications that are the basis for initial interventions. Each skill to be mastered and/or each resource to be obtained is commonly assigned one or more strategies or interventions. These are the basis for the written plans to be signed by the client and the practitioner (Anthony et al. 1987).

The primary rehabilitation intervention strategies employed in this approach are skill acquisition and resource development. Skill acquisition involves direct skill teaching, and is employed when the functional assessment indicates that the client does not have the required skills to achieve the desired goals. This technique leads the client through a series of instructional activities to the point where the client can use the newly acquired skill. The resource development approach is a step-by-step process to overcome the barriers to using the new skill in the particular environment of choice. Resource development strategies involve resource coordination or modification. In resource coordination, a preferred resource is selected, arrangements for its use are made, and supports are obtained and provided in the employment of the needed resource. Resource modification involves adapting existing resources so that they meet the needs of the client (Anthony et al. 1987). This may entail negotiating with a program to make resource adjustments to fit the client’s functional objectives.
In the late 1980s, Danley and Anthony developed the choose-get-keep model of supported employment. They recognized the importance of consumers being involved in the process of achieving employment, rather than being placed in a job. This process involves consumers in choosing, getting, and keeping a job that is consistent with their interests, preferences, skills, and aspirations. This approach includes assisting the client in the job choice, helping the client to develop job-seeking skills, and teaching appropriate job behaviors, such as dressing appropriately and being on time for work. Clients are helped to obtain a job and then provided with the necessary supports for performing the job once employed (placed). The choose-get-keep model involves consumers much more in the decision-making about securing employment. In the get phase, employers are identified, contacted, and interviewed with obtaining employment being the ultimate goal. In the keep phase, the client applies appropriate work behavior skills as well as technical abilities to do the job. This model replaced the practice of training clients, and then, placing them in jobs or what was called the train-then-place approach, which was the traditional approach to vocational rehabilitation of getting clients ready for competitive employment.

The research of the BU model, specifically, the choose-get-keep model of supported employment has been limited. However, the technological orientation and beliefs have been the foundation for a number of programs and other models, which have reached the level of EBP, specifically supported employment.

Peer Support Approaches
Peer support approaches encompass services and supports that are provided by individuals who have a severe mental illness to other individuals with similar disorders. This psychotherapeutic approach is recovery oriented as it engenders empowerment and is based on a belief of consumer self-determination. The underlying assumption of peer support approaches is that those who have shared common experiences are in a better position to offer supports to each other in a safer environment than those who have not had a history of psychiatric treatment (Corrigan et al. in press). Peer support is defined as the provision of emotional support frequently accompanied with instrumental support that is mutually offered by individuals who have both a mental illness and partner together with the specific intention of bringing about social and personal change (Gartner and Reissman 1984). Within the domain of peer support services, there are two approaches: mutual support or self-help groups and peer provided services.

Mutual aid or self-help groups are usually initiated by peers who voluntarily join with others like themselves to mutually assist each other to satisfy a common need or problem (Katz and Bender 1976). These groups instill hope, and offer information and opportunities to mutually help the members. Typically, these are face-to-face groups, but recently there has been a development of internet peer support groups. The most well-known of peer support groups for individuals with psychiatric disabilities are GROW, Schizophrenia Anonymous, and Depression and Bipolar Support Alliance. The research that has been conducted on self-help has not been able to determine its effectiveness, as the use of randomized designs is antithetical to the notion of voluntary participation in self-help groups. However, less rigorous studies, i.e., those employing pre-post test designs or correlational studies, have found benefits derived from participation in these groups (Solomon and Draine 2001).

Peer provided services are provided by individuals who self-identify as a person who is receiving or has received services for their mental illness, and who then delivers his services to others with a similar psychiatric disorder. There are three types of services that fall within this categorization: peer run or operated services, peer partnership services, and peer employees. One of the primary differences among these three approaches is the amount of control and decision-making over the operation and nature of the service provision. In peer operated services, peers have total control over the administrative operation and functioning of the service, whereas with partnerships these functions are shared with nonpeers. Frequently, the types of peer provided services have been drop-in centers, case management services, and crisis programs. With peer employees, the amount of control and power that they have in an organization vary with the position held, as is the situation with nonpeer employees. There has been limited research on peer provided services, but the few randomized clinical trials (RCTs) that have been conducted have found positive outcomes, with no detrimental effects (Corrigan et al. in press). These services are being promoted by SAMHSA and were identified by the New Freedom Commission as an emerging best practice, as there are not enough RCTs to achieve the level of EBP.

Recovery and Rehabilitation
With the publication of the first Surgeon General’s Report on Mental Health (U.S. Department of Health and Human Services 1999) and the final report of the US President’s New Freedom Commission on Mental Health (2003), the idea of recovery among those with SMI has gained prominence and achieved legitimacy, although consumers have been writing about this since the 1980s. These reports, with their authority of government documents, have stimulated the transformation of mental health service delivery to that of a recovery orientation. Thus, the idea of recovery is having a major impact on both mental health policy and practice in the US SAMHSA has issued a consensus statement on the definition of recovery and the fundamental components of recovery. This statement emerged from an expert panel of consumers, family members, providers, advocates, researchers, academicians, managed care representatives, accreditation organization representatives, state and local public officials (see Table 97–2 for SAMHSA’s consensus statement of mental health recovery).

Unlike the medical approach, recovery does not require individuals with SMI to achieve a total elimination of symptoms and related deficits resulting from the disorder, and consequently, may not necessitate a reduction in the need for medical care. Recovery is different from rehabilitation. Rehabilitation refers to services and technologies that are delivered by mental health providers to help consumers and their families improve their functional capabilities and ultimately the quality of their lives (Barton 1998, U.S. Department of Health and Human Services 1999). Recovery is a “lived experience of persons as they accept and overcome the challenge of disability” (Deegan 1988). Recovery has been
Mental health recovery is a journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice while striving to achieve his or her full potential.

### Fundamental Components of Recovery

- **Self-direction:** consumer leads and chooses direction of recovery.
- **Individualized and person-centred:** recovery varies by an individual’s strengths, needs, preferences and experiences.
- **Empowerment:** consumers have the authority to participate in all decisions that affect their lives.
- **Holistic:** recovery encompasses all aspects of one’s life, including mind, body, spirit, and community.
- **Nonlinear:** recovery is one of growth, setbacks, and learning from experience.
- **Strengths-based:** recovery builds on personal strengths, capacities, resiliencies, talents, coping abilities and personal worth.
- **Peer support:** mutual support from other consumers is essential to recovery process.
- **Respect:** community, systems, and societal acceptance and protecting rights, along with self-acceptance.
- **Responsibility:** consumers have a personal responsibility for their own self-care and journeys of recovery.
- **Hope:** hope is the catalyst for recovery and can be fostered by others.

### Table 97–3

**Examples of Recovery Definitions**

- “Recovery from mental illness is the process of healing the effects of (a) one’s illness and its consequences, (b) the social stigma attached to the illness, and (c) the iatrogenic effects of treatment interventions…Recovery implies a process of retrieval (regaining what was lost because of one’s illness and its treatment) and a process of discovery (moving beyond the illness and its limitations)” (White et al. 2005).
- “Recovery involves the development of new meaning and purpose in one’s life as one grows beyond the catastrophic effects of psychiatric disability (Anthony 1993).”
- “A personal process of overcoming the negative impact of a behavioral disability despite its continued presence…recovery is a process by which an individual with a disability recovers self-esteem, dreams, self worth, pride, choice, dignity, and meaning…not tied to symptom relief…relapse may be part of the process” (Wilma Townsend, MSW, mental health consumer, consultant, and trainer).
- “Recovery is a process, a way of life, an attitude, and a way of approaching the day’s challenges. It is not a perfectly linear process. At times our course is erratic and we falter, slide back, regroup and start again…The need is to meet the challenge of the disability; the aspiration is to live, work and love in a community in which one makes a significant contribution” (Deegan 1988, p 15).

A recovery orientation does not “pathologize” consumers, their aspirations, or interpret goals in terms of their illness, but believes in the capability of consumers and supports them to accomplish their goals and aspirations (see case example of recovery orientation). The impact of recovery on service delivery results in the active participation of consumers in the process, rather than passive recipients of services. Recovery-oriented services are conceived of as believing in and supporting consumers in the process of recovery. A recovery orientation requires a different type of relationship between the provider and service recipient to one in which the providers share power, communicate hope, have recipients set their own goals for service planning, and strengthen recipients autonomy as opposed to increasing their dependence on the service system (Felton et al. 2006).
The practice of recovery varies from traditional approaches in two ways. One, as previously mentioned, is an orientation that is in contrast to the elimination of symptoms and maintenance of community living. Second is the necessity for a simultaneous focus on intervening at both the individual and environmental level. When the goal is to maximize community inclusion, the importance of enhancing supports for community life becomes essential (Davidson et al. 2005). Recovery in its approach and orientation is relatively consistent with psychiatric rehabilitation.

Recovery is also about providers communicating hope. This is in contrast to what is too frequently still communicated to individuals with severe psychotic disorders that they are on a downward course with limited hope for the future, despite the fact that research in the last 20 years has demonstrated that these individuals do recover in a variety of realms (Harding et al. 1987). Hope is essential for motivating individuals to move toward the process of recovery. Recovery-oriented psychopharmacology is the integration of medication with rehabilitative services. In prescribing medication for their patients with SMI, psychiatrists can engage in a recovery-orientation by providing education about the illness and the treatment, teaching self-management skills, and engaging in shared decision-making about treatment (Noordsy et al. 2002).

Psychotherapeutic Evidence-Based Practices

Five psychotherapeutic service interventions are now recognized as EBPs for individuals with SMI along with medication algorithms. These are Assertive Community Treatment (ACT), Family Psychoeducation, Personal Illness Management, Integrated Care of Co-Occurring Mental and Substance Use Disorders, and Supported Employment (SE). These have been endorsed and promoted by the President’s New Freedom Commission, the PORT study of schizophrenia (Lehman et al. 2004), a series in Psychiatric Services, books devoted to these interventions (Drake et al. 2005), and by SAMHSA, which has developed toolkits to assist in their implementation. Although dissemination of these practices has been extensive, for the most part, these EBPs have not been extensively implemented in mental health service delivery systems nationwide.

Assertive Community Treatment And Other Case Management Models

ACT is considered to be a model of case management services for adults with severe psychiatric disorders. Although ACT serves the functions of case management, it goes well beyond traditional models of case management. In order to comprehend ACT, it is best to have an understanding of what case management is as well as some of the more widely implemented models that are more likely to be encountered in the community mental service delivery system.

Background of Case Management

With the advent of deinstitutionalization, the need for case management services emerged. As discharged psychiatric patients entered the community, it became apparent that they needed assistance in navigating a complex and fragmented service delivery system. Given the multiplicity of needs of those with SMI, the services, supports, and resources that they need are provided by a diversity of services and systems.

CSP saw the need for a centralized coordinating mechanism to ensure that those with psychiatric disabilities received the services and supports that they required, and that there was a clearly designated central point of responsibility and accountability. With the passage of such legislation as the State Comprehensive Mental Health Services Plan Act of 1986 (PL 99-660), case management continued to be the central service element of a comprehensive system of care for those with SMI and has grown in prominence ever since.

Case management is essentially the process of identifying, accessing, coordinating, and ensuring that individuals with SMI effectively and efficiently receive the services, support, and resources that they need to live in the community with the greatest degree of independence of which they are currently capable. The core functions of case management are outlined in Table 97–4. The primary goals of case management are to maintain contact with services to avoid decompensation, to increase psychosocial functioning, and to improve the quality of life of persons with SMI and their family caregivers (Corrigan et al., in press). In some cases, case managers may function as enforcers of legal mandates, such as monitoring outpatient commitment or probation and parole stipulations, being a representative payee, or withholding housing, particularly with clients who are substance abusers and/or heavy users of crises services (Solomon 1996a, Monahan et al. 2001). Case management may be delivered by an individual, a pair of case managers, or a team.

Other Models of Case Management

There is a diversity of models of case management (see Table 97–5 for characteristics of case management...
models). The most basic of the models is the broker or traditional approach. Broker case managers engage in all the basic functions, but are usually delivered in workers’ offices. Therapists may provide these functions in the course of doing supportive counseling. If all the provider does is case management services, then the caseloads are extremely high. This service is one that generally consists of information sharing and making referrals, and then, the client is expected to proceed with limited support or assistance to access these resources on his own behalf. This service provides the bare minimum of case management, and is not very effective with persons with SMI who require additional help in achieving these case management goals. However, given limited financial resources, this model is still widely offered, especially with individuals who are assessed as relatively high functioning.

Clinical case management is designed whereby a therapist serves as a case manager, thus, engaging in both clinical and administrative functions. While this approach makes good conceptual and clinical sense, given the integration of these primary functions, it does not, however, work very well in reality (Sullivan and Rapp 2002). This model requires a skilled therapist who usually does not have either the time or the interest in engaging in broker case management activities. Furthermore, reimbursement of these functions by managed care companies for this service by a therapist is problematic. Commonly, the term clinical case management is employed for essentially broker case management with supportive counseling, as opposed to the provision of psychotherapy.

Strengths case management is based on the belief that individuals who are successful in living in the community have the ability to develop their own potential and to access the needed resources that enable them to reach their own goals. This model focuses on a person’s strengths rather than deficits, and makes use of an individual’s own natural support system to assist in community integration. In this model, case managers do more than broker services; they deliver services to clients in the community. They help individuals with SMI to identify, obtain, and maintain the environmental and personal resources that they need to live, work, and participate in the community. The approach is for case managers to teach clients to access the resources that they need to live in the community of their choice. The philosophy of this model is that persons with SMI can learn, grow, and change, and that the community is viewed as a resource, not a barrier (Sullivan and Rapp 2002).

The rehabilitation case management model was developed by the Psychiatric Rehabilitation Center at BU. The rehabilitation case manager assists clients by negotiating for services, teaching personal skills, and developing environmental supports to overcome personal and environmental barriers to achieve their own goals (Farkas and Anthony 1993). This model serves the functions of brokering, as well as engaging in rehabilitation.

Intensive case management (ICM) arose as a result of the recognition that the broker model was ineffective with many individuals with SMI. ICM is delivered in the community where clients live and work. In contrast to a broker model, this service model has lower caseloads, engages in assertive outreach, and assists clients in meeting their needs so that they can live as independently as possible in the community. The service elements of this model are not particularly well specified (Schaedle and Epstein 2000). This model is widely implemented, and has borrowed some elements from ACT, specifically delivering services in the community and assertively reaching out to clients.

### Description of ACT

Although ACT was developed in the early 1970s as an alternative to hospitalization for individuals with SMI, it was not until the 1990s that this model was widely implemented. This model, developed in Madison, Wisconsin, was originally called Training in Community Living, and today goes by such names as continuous care teams, full service support, assertive outreach, and mobile treatment teams (Bond et al. 2001b). The intention of this model was to transfer all functions served by a long-term psychiatric hospital to the community. Consequently, ACT is often described as a hospital without walls.
The goals of the model are to reduce hospitalization, increase psychosocial functioning, decrease psychiatric symptoms, and improve life satisfaction and quality of life. The specific tenets of this model are that the locus of care is the community with treatments and supports being comprehensive; and that treatments must be designed to be flexible and individualized to meet the diversity and the ever-changing needs of those with SMI (Test 1998). The notion is that teaching skills in vivo reduces the need to generalize skills learnt in one environment to another in which they will be used. In contrast to other models of case management, this is a full service extremely comprehensive program model, with case management being a component of the service. The case managers function as “assertive resource coordinators” (Test 1992). This program is reserved for the most difficult to manage clients, for example, those who have had extensive stays in hospitals and/or living on the streets, and who have problems with substance abuse or encounters with the criminal justice system. Estimates are that ACT is most appropriate for 10–20% of those served in the public mental health service delivery system.

One of the central features of the model is that the service is provided by a multidisciplinary team, comprised of a psychiatrist, nurse, other specialists, and case managers. Frequently, social workers and rehabilitation counselors are also members. The type of specialists included on the team are contingent on the characteristics of the clients being served and the targeted service goals, such as substance abuse counselors, employment or benefit counselors. Caseloads are relatively low, one staff serves 10–12 clients, with teams serving about 120 persons.

The team is the primary provider and responsible entity for all services, rehabilitation, and treatment. The program is self-contained and offers all services that their clients need on an integrated basis. The team meets daily to ensure that all team members are up-to-date regarding each client’s clinical and psychosocial status. The team members provide medication, clinical care, supportive counseling, skills training, crisis intervention, assistance with benefits, housing acquisition and maintenance, employment assistance, and specialized services such as substance abuse treatment. Anything that clients need to live successfully in the community is provided by the team. The team is available 24 hours a day 7 days a week. This service is also considered a time-unlimited service, although research has indicated that this policy can be modified. However, it is necessary to have a modulated transfer process that ensures a smooth transition with the possibility that clients can return if necessary (Salyers et al. 1998).

By virtue of being a full service model, ACT is not contingent on the availability of resources in its service environment. This is in contrast to other case management models that are dependent on services and resources in the community. ACT programs generally need to rely on local communities for housing, but for little else.

There have been a number of modifications to ACT programs that have been designed to serve specialized populations or to target a specific objective, such as increasing employment. For example, ACT teams have been developed for forensic clients to assist either in community reentry or in diversion from the criminal justice system (Solomon 2003, Solomon and Draine 1995). ACT teams have also been enhanced with the inclusion of family members or family interventions in order to provide support and education for families of clients served by the team. In addition, ACT teams have been comprised of consumers, thus, using the model as a consumer provided service. Others have reconfigured the staff complement of the teams and, thus, employ fewer staff and serve fewer clients. Even when a change in staffing has been made, psychiatrists are always included on the teams. ACT has served as a basis on which to build other specialized programs for adults with SMI, as for example, the addition of social skill training and SE.

ACT has been widely disseminated. The National Alliance for Mental Illness (NAMI) has distributed manuals to assist in the implementation of this program model. NAMI’s objective is that all states will establish a policy to develop ACT programs in all communities across the country.

**Case Example: ACT**

Teresa is a 43-year-old woman who has major depressive disorder with psychotic features, co-occurring alcohol dependence, and a history of numerous psychiatric hospitalizations. For over a year, Teresa lived between a homeless shelter and the streets. She had a broker case manager at a local community mental health agency, but had not attended a psychiatric evaluation with the psychiatrist because she missed three scheduled appointments. Teresa hoped to move out of the shelter, and her case manager informed her that in order to proceed with an application for housing, she needed a copy of her birth certificate, social security card, proof of income, and photo identification. However, Teresa’s purse containing these items was stolen at the end of the summer when she spent several months sleeping in a local park. Teresa’s attempts to get a new photo id failed as the Department of Motor Vehicles required copies of a birth certificate and social security card. Discouraged about remaining on the streets indefinitely, Teresa’s drinking escalated and her psychotic features became more prominent, landing her in the hospital. At the hospital, she was referred to an ACT team, who met her at the shelter. The psychiatrist on the team worked with her to determine an effective regime of medication, while the substance abuse counselor assessed her readiness to quit drinking, and the case manager facilitated Teresa’s scheduling and getting to requisite appointments as well as obtaining her photo identification, birth certificate, and social security card. Within a year of receiving ACT services, Teresa’s psychiatric symptoms have stabilized, her drinking has decreased, and she has moved out of the shelter into an apartment. The ACT team negotiated with a local landlord by ensuring that they would remain involved in Teresa’s treatment, and then, used Teresa’s motivation to obtain housing as leverage to encourage her abstinence from alcohol. The ACT team meets with Teresa at her apartment on at least a weekly basis to ensure that she maintains her sobriety and her recovery.
Evidence of ACT and Other Case Management Models

It is important to note that there have been specific criticisms leveled at the models of case management other than ACT, with others leveled at ACT (Gomory 2004). Stein (1992) noted that there are structural problems with case management models, other than ACT. These models do not have a multidisciplinary team approach, which Stein believes to be essential to treat and care for the complex needs of persons with SMI. Most case management models are dependent on resources that are either unavailable or in insufficient supply in the community system of care. Some critics assert that too much responsibility has been placed on case managers for fixing an uncoordinated, underfunded, and fragmented mental health service delivery system. A latent assumption of case management programs is that they will be able to compensate for the lack of needed community services and resources. However, case managers frequently do not possess the diversity of skills required to correct for these system deficiencies nor do they have the power to change the established system of care (Stein 1992).

A number of studies have evaluated the different models of case management with regard to both system, e.g., rehospitalizations and reincarcerations, and clinical and psychosocial outcomes, e.g., symptoms and social functioning. However, most studies, particularly employing RCTs, have been conducted on ACT or ICM (Mueser et al. 1998). Furthermore, ACT is easier to research as it is a more specified model, and currently, there are a few measures for assessing the fidelity of the implemented model to ensure that new and existing programs achieve the standards of ACT.

There have been numerous reviews, both narrative and meta-analytic, of research on various case management models. Based on these reviews, the conclusions have been quite consistent. ACT, as compared to other models of case management, results in increased likelihood of maintaining individuals with psychiatric disabilities engaged in service, higher degrees of stability in housing, reductions in hospitalizations, and when hospitalized, decreased lengths of stay, and high degrees of both client and family satisfaction. A few reviews did conclude that there were improvements in symptomatology and quality of life. However, most reviews concluded that ACT programs had little effect on social functioning outcomes (Corrigan et al. in press). In order to obtain benefits on specific outcomes, such as vocational or substance abuse outcomes, services need to be directed toward that specific objective by specialized service elements and by the inclusion of specialists on the team. Research has also determined that ACT programs are more effective if they have greater fidelity to the original model (Bond et al. 2001). Reviewers have questioned whether the positive outcome of reduction in hospitalizations is due to the intervention being more coercive than other forms of case management and, therefore, resulting in an increase in medication adherence. However, there has been limited research on adherence to medication in these models.

For those reviewers who assessed the cost-effectiveness of ACT, they determined that the program was effective. However, this was primarily attributed to the reduction in hospitalizations or in length of stays when hospitalized. There are those that caution that as systems come to rely less on hospitals for the care of SMI, ACT will result in less of a cost differential with other case management models, such as ICM (Latimer 1999). With the costliness of ACT and with fewer cost benefits, there may be less incentive for mental health authorities to implement this intervention, even though it is considered an EBP.

Reviews that have assessed other forms of case management, excluding ACT, have come to very different conclusions. These other models, usually broker or intensive case management, increase the likelihood that clients remain in treatment, but frequently result in increased hospitalizations and longer lengths of stay when hospitalized, and in some cases result in an increase in the use of mental health services (Corrigan et al. in press). These outcomes are not surprising since these models are not full service models and have a heavy reliance on other services and resources in the community. Thus, outcomes of case management are very much affected by the service environmental context in which they are embedded.

Family Psychoeducation

Family Psychoeducation is considered an EBP for working with the families of persons with SMI. In order to understand Family Psychoeducation and other family treatment models, it is important to first comprehend the need for family interventions in general.

Need for Family Interventions

Ever since deinstitutionalization, family members have become caregivers and de facto case managers. Estimates are that 30–60% of adults with SMI live with their families (Carpentier et al. 1992). This shift in the locus of care has resulted in emotional and financial burden to family members, regardless of whether their relative lives with them or not. Consequently, professionals have increasingly recognized the importance of families in the care of their clients and the necessity of supporting families in caring for their relatives with SMI. However, families frequently do not have the knowledge or skills to undertake these responsibilities. As a result, there has been a growth in family educational interventions. These interventions fall within three domains: family psychoeducational interventions, family education, and family consultation.

Description of Family Psychoeducational Interventions

Family psychoeducational interventions emerged in response to family environmental stress research, which found that patients recently discharged to families with high expressed emotion (EE), i.e., highly critical, hostile, and emotionally overinvolved, had a high likelihood of psychotic relapse and subsequent rehospitalization (Brown et al. 1958, Brown et al. 1962). Regardless of the intellectual controversies around EE findings continuing to blame the family for the exacerbation of their relative’s illness, the findings were an impetus to the development of psychoeducational interventions designed to assist families in coping with disturbing, distressing, and difficult behaviors of their relatives with SMI. The promotion of these interventions has been based on the assumption that behavioral competencies, adaptive coping, problem solving, and communication skills, along with emotional support can assist families to reduce their stress...
and, hence, environmental stress. As a consequence, patients, specifically those with schizophrenia, who have biological vulnerability to environmental stress will protect them from exacerbation of their illness, with this protection ultimately preventing relapse and rehospitalization. Although the initial research was on patients with schizophrenia, a recent review by Butzlaff and Hooley (1998) concluded that although EE is a robust and significant predictor of relapse in schizophrenia, it is an even stronger predictor for those with affective disorders.

Family psychoeducational interventions were developed by mental health professionals, frequently by psychiatrists. These interventions are a combination of educational and therapeutic service elements. Given that these interventions were based on the EE construct, these programs have the common goals of reducing relapse and improving the quality of life for both the family members as well as the relative by enhancing the family member’s capability of managing their relative’s illness. Initially, these interventions were designed for high EE families, but were relatively quickly available to low EE families as well. Although they vary in program content and structure, all provide information about diagnosis, symptoms, signs, etiology, course and treatment, including medication and their side effects. These programs are generally designed to teach problem-solving and coping strategies, management and communication skills to family members. These educational interventions are provided as part of an overall clinical treatment package; therefore, the relative with SMI is required to be in treatment. These interventions usually last at least 9 months, but may go as long as 5 years. These psychoeducational programs are delivered by a team of professionals from a variety of disciplines, including psychiatry, social work, psychology, and family therapy. The major focus for these interventions is on outcomes for the individual with SMI, and secondarily, for family members.

These interventions vary in their theoretical orientation; program elements including the location of the service, i.e., family’s home, clinic, hospital or elsewhere; length of service and credentials and qualifications of the provider(s); the content emphasized and the information provided; the degree of emotional support; the focus on problem-solving skills, communication skills, and behavioral management; the use of multiple-family versus single-family approach; and approach to delivery of information, such as degree of didactic information, skill teaching, and role playing. Lam (1991) identified the common elements in the various models of psychoeducation (see Table 97–6).

### Table 97–6: Elements Common to Psychoeducational Models

- Positive approach believing in the capability of families
- Highly structured intervention
- Teaching coping skills and strategies
- Supporting the development of clear interpersonal boundaries within the family
- Education about the illness and its course
- Employment of a behavioral approach
- Teaching family communication techniques

Research on the various models of family psychoeducation has not resulted in determining that any particular one is superior to another. It is suspected that since the models have so much in common, such a distinction is not possible. However, McFarlane (2002) multiple-family group approach has been widely promoted. SAMHSA’s draft EBP toolkit uses McFarlane’s model.

### Case Example: Family Psychoeducation

Jane is a 25-year-old woman who was diagnosed with schizophrenia at the age of 23. Due to her illness, she was unable to maintain her corporate job and apartment in the city and ended up moving into her parents’ house. While they were initially supportive of Jane, her parents soon grew tired of what they perceived to be her lack of motivation and laziness. Within a year of living together, her parents began to criticize, nag, and threaten Jane with eviction in an attempt to motivate her to return to work. Every few months, these disagreements would escalate into open and hostile conflicts that would result in shouting matches between Jane and her mother, lasting several hours long. Following these conflicts, Jane would lock herself in her room, stop eating or taking her medication, and within a few days, Jane would experience psychotic symptoms and suicidal ideation, prompting rehospitalization. After her fourth hospitalization in 2 years, Jane’s therapist recommended that she and her parents participate in a family psychoeducation program in conjunction with her existing treatment. Despite Jane’s initial reluctance, she and her parents, feeling at their wit’s end, eventually agreed to participate in the program.

For the first time, Jane’s parents were provided with information about the signs, symptoms, and behaviors associated with schizophrenia, and began to understand that what they had perceived to be Jane’s lack of motivation was actually symptomatic of her illness and the side effects of her medications. Her parents were also provided with the opportunity to grieve the loss of the hopes and dreams they had had for their daughter and, subsequently, to accept and support her new goal of obtaining part-time employment. Jane and her parents worked together to improve communication, reduce conflict, and start problem-solving as a family. Jane continues to live at home, reports a significantly improved relationship and enhanced communication with her parents, and has not been hospitalized for over a year.

### Effectiveness of Family Psychoeducation

There have been at least 14 narrative and meta-analytic reviews of family psychoeducation, and almost all have consistently concluded that these interventions are effective in either delaying or preventing relapse (Corrigan et al. in press). As a result, they have proved to be cost effective due to a reduction in days of hospitalization. In order to achieve these positive outcomes, these interventions need to last for at least 9 months, as brief interventions have not
been found to be effective. Most of these reviews have not drawn conclusions regarding family outcomes, as the intention of these interventions is to improve the family environment so that their relative with the psychiatric disability does better. Given the large number of studies with consistent positive findings, these interventions have achieved the level of EBP. The majority of the studies have been conducted on samples of families with a relative with schizophrenia, and only a few with depression. Some reviews have noted that these interventions have increased adherence to medication by the relative with a psychiatric disability and, consequently, decreased the potential for exacerbation of the symptoms of the illness (Corrigan et al. in press).

**Family Education**

In contrast to psychoeducation interventions, family education interventions are nonclinical, and their primary objective is to meet the educational and practical needs of the family and to consequently improve outcomes for their relative with SMI (Solomon 1996b, 2000). Many of these programs were developed as grassroots efforts by family members themselves in response to their needs for advice and information to overcome their feelings of inadequacy promoted by encounters with professionals. Families frequently feel that they do not need family therapy, but rather very practical information about their relative’s illness and strategies for coping with it. Family therapy generally takes a pathological or deficit perspective as opposed to a competency perspective. The goals of these educational interventions are focused on the family to decrease their stress and burden, increase their coping skills, and improve their quality of life.

The theoretical basis for many of these programs is a coping adaptation framework as well as a social support approach of a supportive network that helps to buffer stress. NAMI’s Family-to-Family is based on a trauma model of recovery, which views having a relative with SMI as a traumatic event from which one needs to recover (Burland 1998). These programs are usually freestanding community-based and are delivered in nonstigmatizing environments, such as churches, libraries, and other convenient and accessible locations rather than as part of a mental health clinic. In contrast to psychoeducation, they are led by families, although professionals are frequently invited to present on specific topics, such as psychiatrists discussing medications. In some cases, these interventions may be co-led by a mental health professional. These are group interventions that are open to anyone with a relative or significant other who has a mental illness, regardless of whether their relative is in treatment or not. When relatives deny their illness or are resistant to treatment [estimates are that up to 50% do so (Kessler et al. 2001)], families often are in need of assistance. Generally, these groups do not include the ill relative, so that family members can feel comfortable to speak freely. Some groups are focused on specific diagnoses and relationships, such as parents, spouses, and children. These educational programs have a didactic component, sometimes using videos and other informational material, and also a sharing component. In some regards, the didactic components are not very different from those of the psychoeducational interventions. Frequently, these groups have a specified curriculum, as does NAMI’s Family-to-Family. Some have homework assignments that participants are to do between sessions. Given that these are group interventions, participants experientially learn from other group members and also receive support and empathy. Some of these programs have a skill training component, where participants can practice skills in handling situations that they are likely to encounter during the course of their relative’s illness. These are very brief interventions that last anywhere from one session of a few hours or a day to 10–12 sessions, such as meeting weekly for an hour or two. Usually, these groups are offered free of charge or for a nominal fee, as state departments of mental health or local mental health authorities may financially assist in defraying some of the cost.

There have been a few randomized studies, all with some positive outcomes. However, the studies have employed a diversity of outcome measures. Consequently, there is limited consistency in positive outcomes (Solomon 2000). Furthermore, since prevention of relapse is not a target of these interventions, none have demonstrated a reduction in hospitalizations which would accrue cost savings, as psychoeducation does (Solomon 1996b). One study did find improved attitudes toward medication compliance by the relative diagnosed with mental illness (Solomon et al. 1996). But, the number of randomized studies on family education is increasing, and these too are showing positive outcomes (Pickett-Schenk et al. 2006). Therefore, it is likely that these educational interventions may well achieve the status of EBP (Corrigan et al. in press).

**Family Consultation**

Family consultation or supportive family counseling is an individual approach to providing information, advice, support, and counseling, either to a single family member or a family unit (Bernheim and Lehman 1985). This is an attractive intervention for families who have a relative who resists treatment. This is a collaborative approach between the family and the provider. The provider is usually a mental health professional, but may also be a trained family member (Solomon et al. 1997). The provider and family collaboratively decide on the goals to be addressed and develop a plan for achieving the objectives. The consultant is just that, a consultant, not a therapist. The consultant works with the family in a consultative manner to achieve the agreed upon goals. During the course of consultation, the family member(s) is provided with education and information relevant to their current situation and problem-solving skills, and may be accompanied by the needed resources and/or services by the consultant. Families find that having the consultant available on an ongoing basis is extremely helpful (Budd and Hughes 1997). Just knowing that as issues arise, there is someone available to answer their questions is often stress reducing for families. This service may also be provided via the telephone, but is usually provided in person. This is a short-term approach, with only a few sessions that are highly focused on one or two very specific objectives. Termination is mutually agreed upon. When new issues arise, the consultation may resume (Solomon 2000). There has been limited research on this particular intervention, but the empirical evidence does indicate that this intervention has promise (Solomon et al. 1997). Table 97–7 compares
family consultation with family psychoeducation and family education.

**Family Support and Advocacy Groups**

Family support groups involve families voluntarily coming together to provide and receive support, empathy, information, and advice from others who share the common experience of having a relative or significant other with a psychiatric disorder. Families facilitate these groups. The groups are open-ended in terms of intensity or duration of participation and meet in a nonstigmatizing environment. The goals of these groups are to increase knowledge, decrease burden and stress, and increase skills to deal with the illness. These groups also afford an opportunity to engage in advocacy efforts to make changes in policy, services, and practices regarding mental health issues. Most local communities have some family groups available, and mental health professionals have been known to refer family members of their clients to these groups.

There has been almost no research on the effectiveness of these groups, as the use of randomized designs is antithetical to these voluntary groups. Less rigorously designed studies have indicated positive outcomes, such as increased knowledge, improved social support, and decreased burden and stress (Corrigan et al. in press).

**Personal Recovery Management**

Illness Management and Recovery (IMR), an EBP, consists of weekly sessions in which specifically trained providers assist individuals with psychiatric disabilities develop personal strategies to manage their symptoms, cope with their illness, prevent relapse, and subsequently move forward on their own personal recovery. This program was developed as part of the National Implementing Evidence-Based Practices Project funded by Robert Wood Johnson and SAMHSA (Mueser et al. 2006).

The impetus for the development of IMR came from increased enthusiasm for recovery, which led to the “recognition that practitioners are most effective when they empower consumers to learn how to manage the symptoms of mental illnesses and increase control over their own lives” rather than doing for their clients (Gingerich and Mueser 2005, p 397). Based on a review of the research, five service components of the IMR program were identified (Mueser et al. 2006) (see Table 97–8).

Service Components of IMR

1. Psychoeducation about mental illnesses and treatments
2. Cognitive–behavioral approaches for adherence to medication
3. Social skills training to increase social supports
4. Coping skills training to manage symptoms
5. Developing relapse prevention plan

Mueser et al. (2006).

The theoretical basis for IMR comes from two models: the stress-vulnerability model and the transtheoretical model. The stress-vulnerability model poses that course and outcomes of schizophrenia are the result of the interaction of biological vulnerabilities, environmental stress, and ability to cope with stressors. The cycle of stress and vulnerabilities can be broken through teaching illness self-management. Ultimately, the distal goal of recovery can be achieved through the pursuit of one’s own personal goals and managing one’s illness. The transtheoretical model asserts that an individual’s motivation to change occurs over a series of stages from precontemplation, to contemplation, followed by preparation, then action, and finally, maintenance. To facilitate the process of change, intervention strategies need to be directed to the client’s particular stage of change. Motivational interviewing is used initially and throughout the IMR program to assist clients in the development of their personal goals, their recovery vision, and exploring how illness self-management helps to achieve their own goals (Mueser et al. 2006).

Description of IMR
IMR can be provided on an individual or group basis, and was originally designed to take 9 months to complete. More recently, it was indicated that it can be completed in 3–6 months. The curriculums were designed to be weekly, with each session lasting from 45–60 min. The programs have a highly structured curriculum that is comprised of nine topic areas: recovery strategies, practical facts about schizophrenia, stress-vulnerability model and treatment strategies, building social supports, using medications effectively, reducing relapse, coping with stress, coping with problems and persistent symptoms, and getting needs met in the mental health system. The topics are covered using educational, motivational, and cognitive–behavioral teaching strategies. For each topic, there are corresponding handouts. Homework assignments are developed collaboratively with clients at the end of each session. The homework assignments include practicing the skills they have learned, reviewing the information provided, and/or sharing the information with others. A specific homework assignment might be to start a conversation with a coworker or share information with a sibling. Based on client choice, members of clients’ support system, such as family members and friends, are encouraged to participate in assisting the consumer to learn self-management strategies and to pursue their own goals (Gingerich and Mueser 2005, Mueser et al. 2006).

Effectiveness of IMR
Mueser et al. (2002) reviewed RCTs of the individual service components of IMR and determined that the evidence supports the intervention components as EBP. This review found that psychoeducation is effective in increasing knowledge about mental illness; behavioral tailoring was effective in increasing medication adherence; relapse prevention programs reduced relapses and rehospitalizations; and coping skills training and cognitive–behavioral treatment reduced the severity of psychotic symptoms. Each of these intervention techniques is the primary component of IMR. Research on comprehensive illness management programs provides promising evidence for a program like IMR. Since this review, IMR has been pilot tested in two sites in the US and one in Australia, either on a group or individual basis. The pilot data from these sites support both the feasibility and acceptability of IMR, with generally good rates of participant retention. Clients were quite satisfied with the intervention and found it to be helpful in managing their symptoms and making progress toward their own personal goals. With regard to posttreatment outcomes, IMR improved clients’ coping with their illness.
and specifically with their symptoms. Furthermore, the research also demonstrated an improvement in functioning for participants. Recognizing that these data are limited in that this research did not employ a randomized design, and data are from early treatment experience, they provide evidence supporting the promise of this intervention (Mueser et al. 2006).

Integrated Dual Disorder Treatment
Integrated Dual Disorder Treatment (IDDT) is considered to be an EBP intervention model for adults with SMI and co-occurring substance use disorders. In order to understand IDDT, it is important to have an understanding of the prevalence of these disorders and the treatment models that were used prior to IDDT.

Prevalence of Dual Diagnosis
Dual diagnosis refers to the co-occurrence of SMI and substance use disorders (abuse or dependence on alcohol or other drugs). Among persons with SMI, a co-occurring substance use disorder is the most common and clinically relevant comorbidity. Studies have estimated that approximately half of persons with SMI report symptoms of substance use disorders (Kessler et al. 1996). This is likely an underestimate, as people tend to underreport substance abuse and dependence. Co-occurring substance use disorders can significantly impede the accurate assessment and consequent appropriate recommendations for treatment unless explicitly assessed when working with persons with SMI.

Co-occurring disorders often complicate the clinical trajectory and long-term outcomes of persons dually diagnosed with substance use and psychiatric disorders. For example, among persons with SMI, a co-occurring substance use disorder is associated with a number of negative outcomes, such as hospitalization and relapse (of both disorders), violence and criminal justice involvement, and homelessness. Individuals with co-occurring disorders are more likely to experience a chronic course of their illness and to utilize more services than individuals with either a psychiatric disorder or a substance use disorder alone (U.S. Department of Health and Human Services 1999). Despite, or perhaps contributing to, these worse outcomes, only 12% of dually diagnosed persons received treatment for both mental health and substance abuse, and more than half of the adults with these co-occurring disorders received no treatment for mental health or substance abuse, resulting in 2 million adults with co-occurring disorders in 2002 not receiving any form of treatment (Office of Applied Statistics 2004).

Background of Treatment for Dually-Diagnosed Individuals
Co-occurring disorders came to light in the 1980s, and interventions were developed in an attempt to address the problems associated with them. Early treatment models included adding auxiliary traditional substance abuse treatment to standard mental health services. For example, a psychiatrist or therapist would recommend that a client with SMI, such as schizophrenia, supplement their mental health treatment with Alcoholics Anonymous meetings in order to address their co-occurring problem with alcohol. Early attempts at treatment for dually diagnosed individuals almost always involved parallel or sequential services for substance abuse treatment and mental health treatment, requiring clients to contend with the difficult process of navigating two different provider systems in an attempt to piecemeal together what was often a fragmented recovery program. In addition, often the two systems of care promote significantly divergent messages, which enhance the existing disconnect between them. For example, some 12-step programs eschew taking any form of drug, including psychotropic medications. Substance abuse providers frequently believe that mental health issues are actually a consequence of substance abuse and, therefore, will be resolved or alleviated once the substance use disorder has been effectively treated, so that there is no need for psychotropic medications. However, psychopharmacological treatment is often an integral component of mental health treatment, which forces the client to make sense of and incorporate these mixed messages into his or her own program of recovery. As a result, many clients end up dropping out of one program in order to assuage the other, or else may become so discouraged that they drop out of treatment altogether.

Other traditional approaches provide treatment in steps or stages; often a client is only eligible to receive treatment for one disorder after completing the treatment for the other disorder. For instance, receiving mental health treatment may be contingent upon completing a substance abuse treatment program (generally a staged program of inpatient, intensive outpatient, and outpatient services), which is often provided by an altogether different agency. In segregated systems such as these, the staff of substance abuse programs are often unaware of or untrained in how to address co-occurring disorders, which results in the psychiatric disorder being viewed as secondary or remaining neglected or untreated. As such, traditional services are typically fragmented and disjointed. In addition, since relapse is a fairly common occurrence among substance abusers, many clients who are unable to fully abstain from drugs or alcohol end up becoming alienated from both the systems. These uncoordinated attempts have been largely unsuccessful because they fail to provide relevant services that effectively address the needs of dually diagnosed individuals, which can jeopardize clients’ attempts at recovery and increase their risk for subsequent relapse, hospitalization, criminal justice involvement, and other adverse outcomes. Despite this, many of these parallel service systems still exist and continue to provide fractured psychiatric and substance abuse treatment.

Resulting from this disconnect between treatment services and between systems of care, NIMH funded demonstration projects in the late 1980s to develop comprehensive and effective treatment services for dually diagnosed individuals. As a result, many interventions developed since the combination and/or integration of mental health and substance abuse treatment. These integrated services and the philosophy behind them have come to be known as IDDT.

Description of Integrated Dual Disorder Treatment
In an attempt to address some of the shortcomings of traditional services to persons with co-occurring disorders,
interventions have moved toward integrating these services and providing them in a common setting and in a coordinated fashion. Interventions focus on the treatment of both disorders concurrently by the same team of clinicians providing services in one location. While these interventions may take different shapes or forms, SAMHSA's Co-Occurring Center for Excellence has developed 12 overarching principles that are integral to addressing the needs of persons with co-occurring disorders (Center for Substance Abuse Treatment 2006) see Table 97–9 for these principles. Essential to the provision of services to dually diagnosed individuals is the need for integrated screening, assessment, intervention, and systems of care that address both disorders. Drake et al. (2005) identified the main characteristics of IDDT as: services provided by a multidisciplinary team, which should include a mental health treatment team and an integrated substance abuse specialist; stagewise interventions consistent with each client’s stage of recovery; time-unlimited services; and access to comprehensive services (i.e., residential services, SE, etc.).

</table>

There are a number of models of integrated treatment, including individual therapy, group therapy, family therapy, structural interventions (e.g., case management, day programs), procedural interventions (e.g., contingency management), residential or housing interventions, and vocational rehabilitation interventions. Individual therapy interventions generally address mental health, substance abuse, and/or posttraumatic stress, and are usually provided in conjunction with other services. Most of the group interventions that are used in treating dually diagnosed individuals employ a self-help approach and provide information, discussion, feedback, (peer) support, and an expanded social network to participants. Family interventions involve education, support, and skills in order to support family members who are caring for or are otherwise impacted by their relatives’ psychiatric illness and substance abuse. Structural interventions encompass changes in the organization of the health care delivery system, and most commonly include enhancing the intensity and integration of services. Procedural interventions, such as contingency management, involve the provision of incentives or disincentives for specific behaviors and outcomes to reduce substance use. Housing interventions include integrated residential treatment programs to prevent or address homelessness. Vocational rehabilitation services that address social and vocational functioning are often integrated into IDDT programs. In addition, integrated services also encompass pharmacologic interventions that address both the substance use disorder and the psychiatric disorder (Corrigan et al. in press). Regardless of the form of integrated treatment, the overall goal of IDDT is to help clients learn how to manage both illnesses in a complimentary and concurrent manner. Best practices in integrated treatment have emerged from the research on these various forms of IDDT interventions and inform the guiding principles of all IDDT services, which are delineated in Table 97–10.

### Effectiveness of IDDT

The research shows that there is sufficient evidence supporting IDDT in general, as well as several of its components.

#### Case example: IDDT

Andy is a 28-year-old male who was referred to his local CMHC after he began exhibiting symptoms of mania. At his intake appointment, Andy also disclosed that he had been using cocaine on a daily basis for the last 3 months. He was given a provisional diagnosis of Bipolar Disorder and Co-occurring Cocaine Dependence and referred to an unaffiliated residential substance abuse treatment facility, with instructions to return upon completion of the program in order to receive mental health treatment. Despite remaining abstinent from cocaine for several weeks into the program, Andy still found himself with racing thoughts, unable to sleep, extremely talkative, and acting out by engaging in sexual relationships with female residents

---

Drake et al. (2004).
specifically as EBPs. A review of controlled studies of integrated psychosocial interventions between the years 1994–2003 found substantial evidence supporting IDDT as an effective practice for persons with co-occurring psychiatric disorders and substance use disorders (Drake et al. 2004). With regard to the specific principles of IDDT, there is strong evidence supporting integrated treatment, stage-wise treatment, outreach engagement interventions, and motivational counseling. For example, research has found that adding assertive outreach to an intensive integrated outpatient program improved engagement, retention, hospitalization outcomes, and abstinence from substances; and that motivational counseling, even as a brief intervention, reduced substance use and dependence, psychopathology, and hospitalizations when compared with standard treatment or educational sessions or advice (Drake et al. 2004). A review of pharmacological treatments found that the atypical antipsychotic clozapine can be helpful in treating substance use disorders in people with schizophrenia; valproic acid and lithium is associated with improvements in alcohol-related disorders in people with bipolar disorders; and that disulfiram and/or naltrexone have positive effects on alcohol abuse for dually diagnosed individuals (Corrigan et al. in press).

In terms of specific interventions, all forms of IDDT appear to have advantages over nonintegrated treatment. For instance, short-term integrated residential treatment interventions had higher rates of completion, less relapse, and less reincarceration and criminal activity (among persons released from prison) over treatment-as-usual (e.g., substance abuse residential treatment). Long-term residential integrated treatment also had better engagement and more successful discharges over long-term residential mental health or substance abuse treatment alone (Drake et al. 2004). The existing research has found that there is enough evidence to qualify IDDT, both as an intervention comprised of specific components and as an overarching philosophy, as an EBP that provides effective services to persons with psychiatric and co-occurring substance use disorders.

Supported Employment

Employment is often an essential component of the recovery process because of its ability to imbue a sense of hope and meaning into the lives of persons with SMI and contribute to their enhanced integration into the community at large. In order to address the desire of many individuals with psychiatric disorders to obtain employment, a number of interventions have been tried with varying success over the years. SE evolved out of the psychiatric and vocational rehabilitation movements, and has been researched extensively and is now considered an EBP.

Rates of Unemployment of Persons with Psychiatric Disorders

Persons with psychiatric disorders have extremely high rates of unemployment and limited participation in the labor force. In 2005, the unemployment rates of persons with a mental disability (defined as a mental or emotional condition, lasting 6 months or longer that results in difficulty learning, remembering, or concentrating) were 29.0%; however, these rates were only 14.2% when examining rates of full-time, full-year employment of 35 or more hours per week for 50 or more weeks per year. As a result, in 2005, among individuals with all types of disabilities, persons with mental disabilities had the lowest annual labor earnings, the lowest median household income, and the highest poverty rate (Rehabilitation Research and Training Center on Disability Demographics and Statistics 2005). Among adults with SMI, the unemployment rate hovers around 90% (National Institute on Disability and Rehabilitation Research 1992).

Persons with psychiatric disabilities face numerous obstacles in obtaining and maintaining employment, which include, but are not limited to: an inconsistent or interrupted work history; lack of access to information, social capital, and social networks; lack of skills and training; interpersonal difficulties; difficulty balancing psychiatric symptoms and work; side effects from psychotropic medications (sedation, difficulty concentrating, etc.); stigma or bias toward persons with mental illness; and fear of losing disability (SSI or SSDI) and medical benefits (Medicaid). Despite these numerous obstacles, employment still remains an important life goal for many persons with SMI. In addition to providing meaningful daily activity and social networks and connections, work can provide structure and routine into an otherwise unstructured and often isolated existence.

Background of Vocational Rehabilitation

Vocational rehabilitation is comprised of interventions that target work-related skills with the goal of placing
participants in competitive employment. While these programs were initially targeted to persons with physical disabilities, the Rehabilitation Act of 1973 mandated access to services in the state–federal vocational rehabilitation system for individuals with severe disabilities, which included persons with severe psychiatric disabilities. However, the literature shows that the rehabilitation rates of these programs have been much higher for persons with physical disabilities than for persons with psychiatric disabilities and that persons with severe psychiatric disabilities generally have the lowest rehabilitation rate (Andrews et al. 1992). These results may reflect the mismatch between traditional vocational rehabilitation services and the needs of persons with severe psychiatric disabilities, many of whom suffer from cognitive impairments which can impact their ability to obtain and maintain competitive employment (McGurk and Mueser 2004) within a relatively short timeframe and without ongoing assistance and supports, as is generally expected of traditional vocational rehabilitation participants.

Despite this mismatch, a number of employment interventions for persons with psychiatric disorders have been influenced by traditional vocational rehabilitation programs, most notably in their train and place orientation, emphasizing extensive training before placing individuals in jobs. In practice, this translates into the bulk of services addressing the “front-end” of the job search process, such as job readiness skills, social and interpersonal skills training, and basic technical or vocational skills training, rather than targeting job attainment and retention phase, which is when persons with psychiatric disabilities may need additional supports. While this type of strategy may be successful for persons with physical disabilities, it may not be appropriate for persons with psychiatric disabilities, as they often need ongoing assistance navigating the processes of interacting with coworkers and supervisors, as well as balancing psychiatric symptoms, treatment, and medication side effects with their jobs, all of which are integral components of ensuring long-term job tenure.

Traditional vocational rehabilitation programs for persons with psychiatric disabilities included hospital-based work, sheltered work settings, job clubs, prevocational training, and transitional employment. While many of these programs still exist (see Table 97–11 for a summary of settings and approaches to vocational rehabilitation), in general, newer models have been developed to address the fact that traditional vocational programs do not place much of an emphasis on obtaining competitive employment, consumer job preferences, or the integration of persons with SMI with persons without such disabilities. Further limitations of these traditional programs are that many of these programs are time-limited and do not tailor their interventions to specific or individual needs. Many of these approaches are waning and being replaced with newer approaches, specifically SE.

Vocational rehabilitation interventions, which have developed more recently, have incorporated the recovery orientation into their services by focusing on empowerment, consumer choice, and the full integration of persons with psychiatric disabilities into society. SE, which grew out of the psychiatric rehabilitation movement, incorporates all of these tenets. It has become the most accepted model of vocational rehabilitation, and over the past 15 years, it has been one of the most thoroughly researched interventions (Corrigan et al. in press).

### Description of Supported Employment
SE is defined by Public Law 99–506 as “competitive work in integrated settings (a) for individuals with severe handicaps for whom competitive employment has not traditionally occurred, or (b) for individuals for whom competitive employment has been interrupted or intermittent as a result of a severe disability and who, because of their handicap, need ongoing support services to perform work” (Federal Register Title 1988). The major components of SE are: competitive employment, integrated work setting, and provisions for ongoing support. Competitive employment is defined as work that is performed on a full-time or part-time basis, averaging at least 20 hours per week and compensating the employee in accordance with the Fair Labor Standards Act. An integrated work setting is one in which an individual with a disability works in a conventional work setting with other workers who are not disabled and has the opportunity to have ongoing contact with workers without disabilities. Ongoing support refers to the provision of continuous or periodic services that are provided either onsite or offsite in order to promote job tenure and can include transportation, counseling, and mediation between employee and employer.

As a vocational strategy, SE shifts the orientation from train and place to place and train. As a result, programs emphasize on helping clients to identify and obtain a job or quickly as possible in order to engage them and then provide the training and/or supports necessary to maintain employment successfully by problem-solving along the way. This approach reduces the amount of time spent at the “front end” of the job search process, which is often a time when clients become frustrated with the time spent on prevocational training and drop out of the program altogether. Instead, SE assists persons with SMI to obtain and maintain competitive employment opportunities that are consistent with

</table>
their individual preparedness, goals, strengths, and abilities. In addition, services are provided in a collaborative and integrated manner.

In general, an SE team consists of at least two employment specialists who work collaboratively with a mental health treatment team or ACT team to provide integrated care, which is considered a key element of this service. Integrated care means that staff associated with all core services work together to develop an appropriate treatment plan with the client. A typical team consists of employment specialists, case managers, a psychiatrist, a nurse, and a substance abuse specialist (if applicable). Together, the team and client identify the client’s treatment goals and then plan collaboratively on how to best achieve them. To this end, the employment specialist works with clients at all stages of employment, including skills assessment, job search and identification, and finally obtaining and maintaining employment. Clients are also provided with benefits counseling to assist with navigating between public benefits systems and wages/benefits received from employment.

Drake and Becker (Becker and Bond 2002) developed the Individual Placement and Support (IPS) model to standardize SE principles for persons with SMI in order to operationalize, research, and implement SE as an intervention. Many existing SE programs around the country follow the principles of the IPS model (Bond et al. 2001), which also serves as the foundation of SAMHSA EBP Implementation Resource Kit on Supported Employment. The core principles of this model are delineated in Table 97–12. There is relatively strong evidence supporting the effectiveness of the principles of eligibility based on consumer choice, rapid job search, and integration of vocation and mental health (Bond 2004).

**Effectiveness of Supported Employment**

Research has found that the intensive range of services encompassed in SE produce higher rates of competitive employment, longer job tenure, and higher earnings for persons with SMI over traditional approaches to vocational rehabilitation across a broad range of client characteristics and community settings (Bond et al. 2001a). A review of quasi-experimental and RCTs identified the critical elements of SE that are predictive of better employment outcomes: agency commitment and resources devoted to competitive employment; rapid job search approach; individualized job placement based on client preference, strengths and work experience; follow-up supports maintained indefinitely; and close integration of SE with the mental health treatment team (Bond et al. 2001a). These components are in keeping with a psychiatric rehabilitation orientation and its focus on hope and belief in consumer’s recovery.

In order to systematically evaluate the effectiveness of SE, SAMHSA designed the Employment Intervention Demonstration Project (EIDP), which was a multisite RCT of SE in eight locations across the country (Cook et al. 2005). Experimental study groups received SE models of treatment while control groups received treatment as usual (standard vocational services), with a 24-month follow-up for both the groups. The major findings from this large-scale study confirmed SE as an effective EBP for persons with SMI. Participants in the experimental groups were more likely to achieve competitive employment, work more than 40 h in a given month, and earn more money than

**Case example: SE**

Joe is a 48-year-old man living with schizophrenia. Due to his psychiatric disability, Joe has not worked for over 10 years, but finds himself at a point in his life where he would like to seek employment. His symptoms have been stable for the last 6 months and, with the help of his ACT team, he recently moved into his own apartment located in the center of a suburban area. His sporadic work history includes manual labor, construction work, and stock clerk positions at supermarkets and warehouses. His personal hygiene is minimal, and as a result, his appearance is somewhat disheveled and often gets mistaken for being homeless when walking through the center of the town. He also has difficulty rising in the morning due to his combination of psychotropic medications and often sleeps until noon. Despite his desire to return to work, he feels ambivalent about possibly losing his SSI checks and Medicaid benefits. He occasionally looks for help wanted signs on the windows of the three local convenient stores he frequently passes by, but is afraid to ask about employment directly as he feels that people perceive him as “different.” When he does mention his interest in employment to his ACT case manager, she suggests that he meet with the employment specialist (ES) on the team. Joe and the ES discuss his goals, preferences, and strengths, and then focus on finding a part-time job within walking distance that allows Joe to retain his Medicaid benefits and only requires him to work in the afternoons. The ES stresses the importance of appearance at the workplace and, consequently, brings Joe to get a haircut and purchase a dress shirt and slacks for interviews. Within a month and a half, Joe secures part-time employment at a local supermarket stocking shelves. When an issue arises within the first several weeks regarding Joe’s difficulty communicating with his supervisor, the ES intervenes by helping the supervisor understand Joe’s illness and facilitating a conversation between the two men. Joe has maintained this job for more than 6 months.
participants in control groups even when controlling for demographic, clinical, work history, disability benefit status, and potential study site confounders; in addition, the advantages attributed to the experimental groups over the control groups continued to increase during the 24 month follow-up period (Cook et al. 2005). The results from this study also confirmed some of the basic principles of SE. For example, participants who received well-integrated vocational and mental health services had significantly better employment outcomes than those who did not receive integrated services; integrated employment services produced positive employment outcomes regardless of client characteristics, diagnoses, work histories, and level of functioning; and better employment outcomes were associated with more vocational services received (Cook et al. 2005). There is similarly a strong evidence confirming the effectiveness of SE for use with individuals who have schizophrenia and other psychotic disorders (Twamley et al. 2003). Finally, research has also identified that the benefits of SE are lasting, with the average job tenure being 32 months (Salyers et al. 2004).

**Brief Overview of Supported Education**

Supported education is a psychiatric rehabilitation approach for those persons with psychiatric disabilities who would like to return to school, generally for postsecondary education. It involves the provision of services that increase access and retention in postsecondary educational institutions for individuals who have had difficulty attending or completing their education due to a mental illness (Unger 1993). Supported education evolved out of SE and employs many of the same principles, such as integrated services, consumer preferences, provision of services in the community, and individualized and time-unlimited services. The focus of supported education is to assist those clients who desire to pursue education rather than work, which is often the case for younger clients whose educational careers have been disrupted as a result of their illness. Since the typical or modal age at the onset of many psychiatric disorders is in the late teenage years or early to middle 20s, educational careers are often interrupted and/or terminated at that point. The goal of supported education is to provide individuals with psychiatric disabilities with the skills and credentials necessary to eventually obtain competitive employment, without which many of these young adults would end up underemployed or unemployed and impoverished.

The mission of supported education programs is to empower adults with psychiatric disabilities to choose their own educational goals and attain their highest potential by providing opportunities for skill development and collaborative support (Mowbray et al. 2005). While supported education models vary (see Table 97–13), core services include: career planning, academic survival skills, and outreach to services and resources. The principles of supported education include hope, normalization, self-determination, support and relationships, and systems change (i.e., reducing barriers to recovery). In a review of supported education interventions, Mowbray et al. (2005) found evidence that for persons with psychiatric disabilities, these programs increased access to and completion of postsecondary education; increased educational enrollment as well as employment participation; improved self-esteem; and resulted in a decrease in hospitalizations. While supported education has a significant amount of research supporting it as a psychosocial intervention for persons with psychiatric disorders, additional studies need to be conducted in order for it to reach EBP.

**Conclusion**

This chapter has provided an overview of psychiatric rehabilitation principles, practices, and program interventions that are geared at the major life domains: independent living (housing supports will be provided in another chapter), education and employment, personal relationships, health, criminal justice, and spiritual life and recreation. The major goal of these service interventions and supports is to assist adults with psychiatric disabilities to live successfully in the community with as little professional assistance as possible. The strategies employed by the multiplicity of approaches are to develop and/or modify the individual’s skills and environmental supports. The principles and practices of psychiatric rehabilitation ensure that the individual with a psychiatric disability is an integral and central decision-maker in the process of service planning and provision and, consequently, in his/her own recovery process. Client self-determination is valued and emphasized.

Psychiatric rehabilitation providers work in concert with treatment providers, most specifically, the psychiatrist who is responsible for prescribing the medication and clinically monitoring the client. Many of these rehabilitative interventions are designed to enhance the work of the psychiatrist treating this population. The role of the psychiatrist in the rehabilitative process includes being a member of the team, as well as promoting the values of self-determination and taking recovery orientation to serving those with psychiatric disabilities. Furthermore, it is also essential for psychiatrists to provide education, information, and support to those with psychiatric disabilities, as well as their families and support systems. It is important for psychiatrists to be knowledgeable about these community mental health resources in order to make appropriate recommendations and referrals.

Although a number of these program interventions have achieved the status of EBP, while others are considered emerging best practices, these rehabilitative approaches are still available on a limited basis. The support of psychiatrists in the dissemination and implementation of these programs is crucial.
Introduction
A mentally ill woman involved with a self-help group writes to thank a peer who has helped her recover from an episode of hopelessness and despair.

We’ve all known so much pain and so many years of struggling, that I feel we share a bond the likes of which the so-called “normal” world will never know. I consider it a privilege to be associated with people who have survived, and survived, and survived again, but still have the courage, the compassion, and the humanity to keep on striving and caring about themselves and reaching out to touch others in trouble. Although the rest of the world perceives us as different and pretty much useless, I think we’re about as special as you can get. (Deegan 1994)

The letter captures some of the therapeutic aspects of the self-help experience. These include the feeling of not being alone, of bonding with peers who have shared the experience of mental illness. The woman is grateful for role models who have been able to reach out and help others. Viewing these examples of strength in persons with psychiatric disabilities, the writer rejects the world’s stigmatization of the mentally ill and reevaluates with pride her own identity. There is a new appreciation of herself as someone able to transcend the pain and emerge as a survivor.

What is the relation of the self-help enterprise to the practice of psychiatry? Within the field of mental health, concepts such as advocacy, volunteerism, self-help, and consumerism represent interrelated activities that may share common objectives and yet differ substantially in process and impact. Each of these concepts has had some influence on psychiatric knowledge and practice. They designate extraprofessional efforts that, first of all, appear to be helpful to many patients. However, some of these concepts also describe social movements that have far-reaching effects on the funding of basic etiological research as well as services, the shape of mental health law, clinical training and patient-physician relationships, and the parameters and structures of treatment systems. Continuing research on self-help and consumerism may also add considerably to our knowledge of the mechanisms of therapeutic growth.

Advocacy and self-help cover a wide range of mental health-related issues. In this chapter, these concepts are defined in terms of how they relate to a variety of conditions. However, the primary focus is on their application to the population of persons with major mental illnesses, that is, persons who have been psychiatrically hospitalized, have received crisis services, or have manifested functional impairment and a need for prolonged outpatient care. Much of the discussion relates to people who rely on psychiatric services for extended periods of their lives. The involvement of such persons with self-help movements is of considerable interest to the psychiatrists from whom they receive their professional care.

Conceptual Distinctions
Advocacy
Advocacy groups focus on social and legal remedies to improve the lives of the particular constituency they represent. A primary focus of groups operating with a mental health agenda is legislative advocacy. This typically involves active lobbying for funding for research and services. Advocates may also work to promote legislation to protect the rights of mentally ill persons; extend entitlements; mandate insurance parity in order to ensure equal access to benefits of mentally, developmentally, and physically disabled persons; and improve standards and quality of care. Advocacy efforts may involve public education and antistigma campaigns and promoting and publicizing programs with innovative models of treatment and rehabilitation. Advocates may attempt to...
influence the agendas of federal agencies to focus on persons with serious mental illness, accompanied by budgetary advocacy to increase the funding for these agencies. Although tax-exempt groups cannot engage in political sponsorship of candidates, individual members are likely to offer active support for legislators with a favorable voting record on mental health issues.

Currently, there are strong initiatives to ensure that the needs of persons with chronic mental illness will not be lost in the acute care models of most managed care systems. In most cases, lay advocacy organizations will collaborate with professional associations to promote mutual agendas for standards, credentialing, clinical services, and research. This adds the considerable weight of a citizen constituency to what may be perceived as the vested interests of a practitioner group.

Volunteerism
Volunteerism, or work without remuneration, involves the participation of concerned individuals in a variety of unpaid activities that improve the lives of persons with mental illness. These are typically offered by nonprofessionals contributing their time and energy to augment professional services. However, as may be seen in some of the descriptions of citizen and consumer organizations, professionals may also act as volunteers. They may contribute their time to educate the public, lead support groups, serve on boards, or otherwise act in an unpaid advisory capacity.

Volunteerism may involve efforts devoted to the development of ancillary resources for persons with mental illness or the provision of personal services to supplement the professional system of care. A notable example is COMPEER, a nationwide program that trains volunteers to provide social companionship and role models for persons with severe and persistent mental illnesses.

Volunteerism has been considered a uniquely U.S. product, but there is increasing evidence of its application in other countries. In northern Italy, numerous volunteer components. The scope of volunteer activities in these movements of psychiatric consumer advocates.

Consumerism
Consumerism as applied to mental illness is the doctrine that service recipients have essential contributions to make to mental health planning, service delivery, and research. In this context, psychiatric service recipients generally refer to themselves as consumers, the most widely accepted term. However, they are also self-defined as clients, patients, ex-patients, persons who are psychiatrically disabled, persons who are psychiatrically labeled, inmates, and survivors, depending on the orientation of the speaker.

The Center for Mental Health Services (CMHS) of the Substance Abuse and Mental Health Services Administration (SAMHSA) (2001) defines a consumer simply as “an individual, 18 years of age and older, with severe mental illness.”

</tbody>
</table>

Self-Help
Self-help refers to the organization of groups of individuals sharing a common problem who meet for purposes of mutual aid and support, education, and personal growth. Although advocacy may also be included in the agenda, self-help groups primarily focus on relief of personal problems through unburdening, sharing experiences and solutions to mutual problems, role modeling, positive reinforcement from peers, and information exchange. Through these activities, self-help groups improve coping skills and also provide social support. Self-help groups aim toward therapeutic growth and skill development through mutual efforts rather than through professional interventions.

In 1990, it was estimated that between 9 and 12 million U.S. adults used self-help groups (Lieberman 1990). Given the explosion of self-help groups in successive editions of The Self-Help Group Source Book (White and Madara 2002), there may be double that number today. Almost all of these groups deal with mental health-related problems. Included are the primary substance abuse organizations, Alcoholics Anonymous (AA) and Narcotics Anonymous (NA), with almost 100,000 chapters. Their famous 12-step paradigm has been extended to other addictions (Overeaters Anonymous, Gamblers Anonymous, and the like). Parents Anonymous uses the self-help model for treatment and prevention of family violence. Other groups deal with bereavement; victimhood; physical and developmental disabilities; parenting; and social discrimination issues relating to gender, sexual orientation, or ethnicity. There are also specialized groups for adoptees, adult children of alcoholic persons, victims of sexual abuse, and persons who have suffered a range of other human problems. After the World Trade Center (WTC) disaster of September 11, 2001, a surge of local face-to-face WTC groups were organized by survivors and families and friends of victims to deal with the traumatic effects.

Included among the self-help groups outside of the professional system are those for people coping with serious psychiatric disorders. Long-term general organizations such as Recovery Inc., and GROW (not an acronym), and those that are diagnosis-specific, tend to be oriented toward mutual support and aid rather than political advocacy. However, there is some overlapping membership in the growing movements of psychiatric consumer advocates.
Most persons identified as consumers typically have been psychiatrically hospitalized or have received outpatient care for a serious psychiatric condition. As persons who have experienced mental illness and who have been exposed to various treatment and rehabilitative modalities, consumers have long been considered to be valuable judges of whatever will best serve the needs of their peers, both by SAMHSA (Substance Abuse and Mental Health Services Administration 2001) and the National Association of State Mental Health Program Directors (NASMHPD) (1989). Consumers who serve in this capacity may have various levels of functioning. Although some may have a diagnosis of schizophrenia, these are individuals who are articulate and rarely cognitively disabled (Frese 1998). Indeed, many consumers have superior talents in writing, organizing capability, or in various areas of technical skill.

For more than a decade, consumer input has been solicited by government agencies at all levels of knowledge development and service building. This may range from formulating basic research questions to consumer roles in design, interviewing, and data analysis; from program monitoring and evaluation to state and local systems planning (Trochim et al. 1993).

Targeted requests for grant applications from federal and state authorities solicit consumers in remission for service delivery roles both as staff members in professionally run services and as operators of alternative services for persons with mental illness. Evaluations of some of these enterprises are discussed in the section on Research. In the following section, commonalities and differences of citizen, family, and consumer, and strictly consumer organizations are described. A sample of major organizations with their differentiating characteristics and Websites is indicated in Table 98–3.

Until recent years, mental illness has been different from these other conditions in the composition of its advocacy groups. Encompassed within the framework of safeguarding...
human rights and the global promotion of mental health, advocacy for persons with severe psychiatric disorders was largely the province of concerned citizens rather than that of acknowledged stakeholders whose own lives are invested in treatment and cure. For many years, former patients and relatives who participated in these movements maintained a relatively low profile. Internalizing societal (and often professional) stigma, they rarely acknowledged their own experiences in public advocacy efforts or in leadership roles. The history of mental health advocacy in the United States has, therefore, had two major developmental stages: citizen organizations, and since the late 1970s, family and consumer organizations. With respect to the latter, we also discuss the radical antipsychiatry movement that arose in the 1960s among some former patients, which analysts note has evolved into a patient-based consumerist movement today (Rismiller and Rismiller 2006).

Citizen Advocacy Organizations

Mental Health America (Formerly the National Mental Health Association)

Mental Health America (MHA) changed its name from the National Mental Health Association in 2006. MHA has been the major advocacy group for persons with serious mental illness until the organization of the National Alliance on Mental Illness (NAMI, formerly the National Alliance for the Mentally Ill) in 1979. Founded by a former mental hospital patient, Clifford Beers, MHA in previous years was a strong advocate for people with serious mental illness, but its main mission was aimed at improving mental health in the population at large, with a strong emphasis on primary prevention. Examples of activities by local branches included conferences on sexuality, police training to deal with interethnic conflict, support groups for newly widowed persons, and training volunteers to befriend troubled schoolchildren or to work with victims of natural disasters.

In most areas, the local MHA branch was the major umbrella organization linking professionals with interested citizens, facilitating joint advocacy efforts and providing mental health education for the public. Mental health professionals have been actively involved in governance boards of the lay organization, and there are friendly affiliative relationships with professional societies. In contrast to self-help groups, MHA support groups traditionally were led by volunteer professionals, and persons needing further help were urged to use psychotherapists in the mental health system. Today, many more MHA affiliates are offering space and resources for peer-led groups that function independently of the host organization. MHA has taken increasing interest in consumer groups, has a CMHS-funded Consumer Supporter Technical Assistance Center, and provides affiliative support to the oldest and strongest resource center for consumers, the National Mental Health Consumer Self-Help Clearinghouse (NMHCShC) in Philadelphia. Despite their broad-based interests, MHA groups have always lobbied for legislation for persons with serious mental illness and developmental disabilities at both state and national levels. For many years, they were the major citizen voice, working in tandem with professional societies and persons interested in mental health law and patients’ rights.

Bazelon Center for Mental Health Law

The Judge David L. Bazelon Center for Mental Health Law, formerly the Mental Health Law Project, was organized in 1972 to halt abuse and neglect in state mental hospitals and training schools for persons with mental and developmental disabilities, and to prevent exclusion of disabled children from publicly funded education. Its current agenda is much more comprehensive. In addition to its basic focus on protecting patients’ civil liberties, the center provides legal resources to combat exclusionary zoning and rental policies; promotes patients’ access to health care, social services, and income support; reforms state systems of care; and helps generate a continuum of community services for persons with psychiatric and developmental disabilities. Working in the courts and in legislative and policy arenas, the Bazelon Center offers legal assistance to consumers, other advocacy groups, and policymakers.

State Protection and Advocacy Centers

State Protection and Advocacy Centers (P&As) are federally mandated to protect disabled persons from neglect and abuse and to protect their rights in institutional and community settings. Initially passed by the Congress in 1986 and reauthorized in 1991 (PL 102-173), the legislation is now known as the Protection and Advocacy for Individuals with Mental Illness Act, extending rights already afforded to persons with developmental disabilities. The law provides grants to existing P&As for the developmentally disabled. Much of their work involves grievance casework for individuals, although they also initiate lawsuits to upgrade institutional conditions. Many P&As also view their mission as reforming the service delivery system, which may include shifting resources from institutional to community vendors. All 50 states, the District of Columbia, and five territories have federally funded programs under the Protection and Advocacy for Individuals with Mental Illness Act. State P&As are members of the National Association of Protection and Advocacy Systems.

Stakeholder (Family and Consumer) Organizations

A scientific national survey in 2002 found 7467 groups and organizations run by and for mental health consumers and/ or family members in the United States. Included were 3315 mutual support groups, 3019 self-help organizations, and 1133 consumer-operated services (Goldstrom et al. 2006). Some of these are described later, primarily in terms of membership and national influence.

The National Alliance on Mental Illness (NAMI), Formerly The National Alliance for the Mentally Ill

The organization of NAMI has been termed one of the most important events in the history of U.S. psychiatry (Kaplan and Sadock 1991). Indeed, former NIH director Herbert Pardes has hailed the political influence of NAMI as “the single most positive event in the history of mental illness.” (Flynn 1993, p 8). For the first time, the major psychiatric disorders had their own important national presence, a grassroots constituency of families with a profound commitment to improving services, research, and public awareness and to reducing the stigma of mental illness.
Although local family support groups had been organized in the 1960s, and at least one state family federation existed in 1971 (Shetler 1986), it was not until 1979 that 284 family members convened at the University of Wisconsin, Madison, to form the national organization. Since that time, NAMI has grown exponentially into a powerful movement. Currently, there are NAMI organizations in every state and 1100 local communities around the country. A well-functioning NAMI office in Arlington, Virginia disseminates information and lobbies for research and services at the national level, and 50 state NAMI organizations work for improved services in their individual states.

Like most organizations that are formed by stakeholders rather than interested outsiders, NAMI merges self-help and advocacy. Thus, the basic armature in all localities is mutual support groups and membership education about all aspects of major mental illnesses. Most groups have also engaged in public education; resource development; antistigma campaigns; and service on mental health planning, policy, and governance boards at local and national levels. Consumers and family members are trained to become effective lobbyists and advocates for patients. Professional educators within NAMI have developed models for training family education specialists. NAMI has also had an impact on clinical training. The NAMI Curriculum and Training Network focused on influencing mental health professionals to work with persons with severe mental illness and on ensuring state-of-the-art education in clinical training programs from preservice to continuing education levels. Several national conferences cosponsored by NAMI and the National Institute of Mental Health (NIMH) brought together leading clinical educators, researchers, and practitioners with family member–mental health professionals for concept development and curriculum planning in the core professions (Lefl ey and Johnson 1990, National Institute of Mental Health 1990).

A major phenomenon is the NAMI Family-to-Family program, developed by a psychologist–family member as a 12-week educational program on major psychiatric disorders (Burland 1998). This manualized program is carefully structured to train family members as educators. They provide some of the content of evidence-based psychoeducational intervention, such as problem-solving and communication skills, as well as understanding the patient’s experience. The program also teaches families how to cope with family burden, avoid overinvolvement, set limits, and see to their own needs and those of other family members. Family-to-Family is available in numerous states with state mental health authority sponsorship, and has been administered to more than 100,000 families.

NAMI also has a program for consumers, Peer-to-Peer. This 9-week course focuses on education, self-help, and recovery principles for people with a major mental illness. It is taught by two consumer-mentors who have received intensive training. Additionally, an antistigma public education program, In Our Own Voice: Living with Mental Illness has received considerable community acclaim. Trained consumer speakers use a nationally produced video to inform the public about the human face of mental illness and the potential for recovery. Consumer feedback from these courses highlight self-determination and empowerment skills. Both of the consumer programs provide the presenters with a salary.

For persons attempting to reenter the traditional workforce, this provides employment experience following a period of disability.

Additionally, NAMI has targeted educational activities for providers with the NAMI Provider Education Course. This 12-week course uses a team of two family members, one consumer, and one professional to educate providers about the actual experience of mental illness. These educational programs, which offer a wealth of materials to participants, are usually funded through state mental health program offices.

On the national level, the family constituency has been powerfully influential in raising research dollars for mental illness. NAMI has successfully lobbied for substantial increases in congressional appropriations for NIMH research on the major psychiatric disorders and helped launch the National Schizophrenia and Brain Research campaign. NAMI cofounded the National Alliance for Research on Schizophrenia and Depression (NARSAD) in 1985 and has generated millions of dollars in research awards through the Ted and Vida Stanley Foundation.

NAMI-sponsored research and publications have had a substantial influence on mental health services. Early survey findings included Care of the Seriously Mentally Ill: A Rating of State Programs (Torrey et al. 1990) and Criminalizing the Seriously Mentally Ill: The Abuse of Jails as Mental Hospitals (Torrey et al. 1992). Most recently, the organization published a comprehensive report that again graded the states on their mental health systems, in terms of infrastructure, information access, services, and recovery supports (NAMI 2006). Although the states received an overall “D” rating, they found examples of innovative programs in virtually every state. Some state administrations used their poor rating to receive additional funds for needed services. In addition, NAMI publishes numerous educational booklets on mental illness, in English and Spanish. Their contents are supervised by members of NAMI’s Scientific Council, composed of psychiatry’s leading researchers and educators.

With a major stake in legislative advocacy at the federal level, NAMI was active in promoting passage of Public Law 99-660, which required all 50 states to develop a comprehensive mental health plan including provision of community care to persons with serious mental illness. The legislation, for the first time, required family and consumer participation on a state advisory council. Reauthorization language linked the approved state plans to the federal block grant, and local NAMI groups became active in monitoring their state’s compliance with the plan’s objectives. NAMI fought for the Protection and Advocacy legislation previously discussed, and the organization was a vocal advocate for the Americans with Disabilities Act. NAMI has been actively working for mental health parity legislation, and for implementation of the Wisconsin Program for Assertive Community Treatment (PACT) as evidence-based practice in all states. The organization was actively involved in the dissemination of the findings of the Schizophrenia Patient Outcomes Research Team (PORT), which recommended specific parameters for prescribed antipsychotic medications (Lehman and Steinwachs 1998). NAMI also helped develop and disseminate the “Guide for Patients and Families” appended to the 1999 Expert Consensus Treatment Guidelines for Schizophrenia (Weiden et al. 1999).
Current advocacy efforts focus on preventing changes to Medicaid that would limit needed services for mental illness, guidance about Medicare part D drug benefits, and funding for the “Mentally Ill Offender Treatment and Crime Reduction Act,” among numerous other efforts. NAMI’s CIT Technical Assistance Resource Center provides help to many communities that are developing programs to train police officers about serious mental illness and the appropriate treatment of potential offenders who appear to be mentally ill. Funding for jail diversion programs and mental health courts are high on the NAMI lobbying agenda. The NAMI Consumer Council is a group of primary consumers who function as a separate interest group within NAMI with a very substantial role in policymaking. Frese et al. (2001) report that during the past several years at least one-quarter of the members of NAMI’s board of directors have been consumers. Its current president (2006), Suzanne Vogel-Scibilia, M.D., is consumer, family member, and working psychiatrist. Thirty percent of NAMI members are consumers. Members of the NAMI Consumer Council generally support the NAMI agenda, but many have overlapping affiliations and common interests with other consumer organizations.

The Federation of Families for Children’s Mental Health

Although this chapter focuses primarily on self-help and advocacy for adults with serious mental illness, mention should be made of the Federation of Families for Children’s Mental Health (FFCMH), a national parent-run federation organized in 1988. Like NAMI, this family movement was organized with joint academic–government support; in this case, the Portland State University Research and Training Center on Family Support and the National Institute on Disability and Rehabilitation Research.

In contrast to NAMI, which generally has focused on severe mental illness and Axis I diagnoses, FFCMH is a broad-based organization that addresses the needs of children and youth with a wide range of emotional and behavioral disorders. In functions similar to those of NAMI, however, the FFCMH is engaged in information dissemination, mutual support, and advocacy for research, prevention, early intervention, family support, education, transition services, and all other services needed by children and youth with emotional, behavioral, or mental disorders and their families. Their focus, like NAMI’s, is on systems transformation. In addition to knowledge dissemination and legislative advocacy, major initiatives are to ensure parents’ involvement in their children’s treatment and the availability of a flexible, affordable, and individualized array of supports to maintain family integrity.

The Federation has been active in legislative advocacy for children, including supporting Public Law 102-321, the Child Mental Health Service Program, and the Family Preservation and Support Services Act (PL103–66). They are currently addressing children’s needs for mental health services in managed care systems.

The FFCMH has collaborated with other organizations to facilitate studies and publish materials on children’s mental health. In conjunction with the MHA, the organization published All Systems Failure, a report providing school-related data on a state-to-state basis, detailing the progress of educational and mental health systems to work together to deal with serious emotional disturbance in children and adolescents. In collaboration with the Bazelon Center for Mental Health Law, the Federation has issued publications on managed care for children, Your Family and Managed Care and A Family Advocate’s Guide. Like NAMI, FFCMH publishes materials in Spanish as well as English, has manualized training curricula, and a corps of Federation-Certified Trainers. Although FFCMH and NAMI share many functional characteristics as an adult organization, NAMI has been progressively driven by consumer roles in policy and decision making. We turn now to the various types of organizations that have been generated and maintained by patients and former patients themselves.

Consumer Self-Help and Advocacy Organizations

Consumer self-help organizations generally merge mutual support with a focus on one of two basic objectives: political advocacy or personal problem resolution and growth. A study of 104 self-help groups of present and former psychiatric patients identified two major service models, which the author differentiated as social movement versus individual therapy. The social movement groups were oriented toward social change and offered public education, legal advocacy, information referral networking, and technical assistance to other consumers. The individual therapy groups offered more “inner-focused” individual change through mutual support meetings with a focus on coping with their illness (Emerick 1990). This distinction is still valid today.

The Depression and Bipolar Support Alliance (DBSA)

A major consumer organization that combines both social movement and therapeutic functions is the DBSA, formerly the National Depressive and Manic-Depressive Association. Like NAMI, the DBSA views mood disorders as primarily biogenic and disseminates public education on unipolar depression and bipolar disorder. The organization has a large network of local support groups and holds annual conferences with professional presentations. There is an emphasis on fighting stigma and promoting basic research with a variety of advocacy efforts, including providing expert testimony for the Congress. National DBSA publishes brochures, books, and videotapes about the treatment of mood disorders. Publications are reviewed by members of the DBSA Scientific Advisory Board, which includes prominent psychiatrists and researchers.

The DBSA has a strong alliance with professionals and an influential role in developing practice guidelines and consensus statements on the treatment of patients with bipolar disorder. Consultants from the DBSA were involved in the Practice Guidelines for the Treatment of Bipolar Disorder (American Psychiatric Association Practice Guidelines 2002). In a major undertaking, the organization convened mental health professionals, policymakers, researchers, clinicians, patients, and families for a national conference to seek solutions for the undertreatment of depression. A consensus statement was published in JAMA (Hirschfeld et al. 1997). This made it available not only to the mental health community but to all physicians who might encounter the symptoms of affective disorders. The organization convened
a large group of mood disorder researchers on the use of placebos in clinical trials. The conference consisted of expert presentations on bioethics, biostatistics, unipolar depression, and bipolar disorder (see Rosack 2002). The consensus statement, published in the Archives of General Psychiatry, underscored that patients’ safety and well-being must come first, but stressed the importance of placebo in developing new treatment options (Charney et al. 2002). The DBSA’s emphasis on informed consent, appropriate placebo usage, and responsibility of pharmaceutical companies suggests that consumer groups may assume an active role to insure informed participation in clinical trials and optimal availability of useful medications.

The Therapeutic Support Group Model
At this writing, the American Self-Help Group Clearinghouse lists approximately 1100 national self-help organizations with thousands of local support groups for specific psychiatric conditions, general mental health, addictions, bereavement, disabilities, abuse, parenting, caregiver concerns, and stressful life situations (retrieved December 20, 2006 from http://mentalhelp.net/self-help). Just a few of the major national organizations for psychiatric patients can be mentioned, excluding groups that specifically focus on addictions. Almost all these groups offer a caring and sharing community, with a focus on attaining emotional maturity, personal responsibility, and recovery from mental illness.

Among the general groups are GROW, an international organization founded in Australia in 1957. GROW in America has a 12-step program to provide skills for emotional growth and for avoiding and recovering from a breakdown. Recovery Inc., founded in 1937, offers a self-help method of will training for people suffering from emotional and mental conditions. They claim that their principles parallel those found in cognitive-behavioral therapy. Emotions Anonymous is another general national organization with a 12-step program to gain better emotional health.

Diagnosis-specific national self-help organizations with local chapters include Schizophrenics Anonymous, which focuses on recovery and uses a 6-step program, along with medication and professional help. Anxiety Disorders Association of America supports groups that deal with phobias, posttraumatic stress disorder (PTSD), and all anxiety-related disorders. The organization lists local professionals providing relevant treatment and also provides a national listing of clinical trials. The Obsessive-Compulsive Foundation offers support groups plus a newsletter, books, audio and videotapes, and an annual conference. Agoraphobics in Motion (AIM) claims to use specific behavioral and cognitive techniques in its support groups. Dual Recovery Anonymous and Double Trouble in Recovery Inc. are self-help fellowships for individuals in recovery from mental illness and addiction.

Panic Survivor and the Panic Center are online support groups for panic disorder. Social Phobics Anonymous is a 12-step telephone group. BPD Central and BPDWORLD provide on-line links and message boards for persons with Borderline Personality Disorder. An interesting type of organization is the National Education Alliance for Borderline Personality Disorder (NEA-BPD). Composed of family members and professionals, NEA-BPD hosts national conferences with leading BPD researchers, and participates in an ongoing funded research project, Family Connections, which offers dialectical behavior training for families.

The Political Advocacy Model
Among some former psychiatric patients, self-help in itself is viewed as a political statement. They increasingly advocate for and receive federal and state funding to develop programs that they believe will speed recovery more effectively than services offered by the professional mental health system alone. A few believe that psychiatric interventions are countertherapeutic rather than helpful. Zinman et al. (1987) gave the essential characteristics of self-help groups as self-definition of needs, equal power of members, mutual respect, voluntary participation, autonomy, and responsiveness to other special populations. The self-help mission is for optimal personal independence with the option of choosing interdependence with other consumers.

For many years, self-help was incorporated in organizations of former psychiatric patients with names such as the Insane Liberation Front (Portland, Oregon) or the Mental Patients Liberation Project (New York) and publications such as The Madness Network News (California). These groups of former psychiatric patients were angry at a system that they thought had abused and dehumanized them rather than helped them. They tended to have strong antipsychiatry views; they were vehemently opposed to electroconvulsive therapy and often to psychotropic medications as well. Many thought that the only valid help for persons who were “psychiatrically labeled” would come from peers who had experienced a similar history of psychiatric hospitalization. Many of the pioneers of the consumer movements developed and provided models for today’s consumer-operated services. An analysis of the evolution of the movement states that today’s antipsychiatry adherents no longer focus on dismantling organized psychiatry but try to promote radical reform in the mental health system (Rismiller and Rismiller 2006).

Although contemporary consumer groups have a common agenda of self-determination, a sociological analysis indicates that former psychiatric patients are still divided in their views regarding the etiology and the validity of the concept of mental illness (Kaufmann 1999). A few still view mental illness as psychogenic or as a social construct, rejecting biogenesis, but most seem to accept a diathesis-stress model and many describe themselves as having a brain disease or “a chemical imbalance” (Kersker 1994). Some consumers are totally opposed to any kind of forced treatment while others have stated that without it, they might not be alive today (Rogers 1994). Some members of the consumer movement think that hospitalization is harmful and would like to eliminate all hospital beds. However, their views are not supported empirically. In the California Well-Being Project (Campbell 1989), a survey of psychiatric clients designed and conducted by consumers and directed by a professional researcher-consumer, more than 50% of the respondents believed that their hospitalization had been helpful, 22% reported both positive and negative aspects, and only 20% found hospitalization harmful.

Former national consumer organizations were disbanded and were largely supplanted by state and local groups networking at annual conferences. They were engaged in coalition building and developing local consumer-run
Government Roles in Consumer Empowerment

A major element in helping the organization of both family and consumer movements is the Community Support Program (CSP) of the federal government. Initially under the NIMH and now part of CMHS, the CSP was organized in 1978 to deal with problems of deinstitutionalization. The federal program focused on developing in each locality a comprehensive continuum of care for deinstitutionalized patients that would include all needed resources for survival, treatment, rehabilitation, and hopefully, a satisfactory quality of life (Stroul 1989). Through targeted grants to state administrations, the CSP fostered public–academic linkages and funded research and demonstration grants for model programs, including case management, crisis services, programs for homeless persons with mental illness, and other innovative community rehabilitative projects.

The CSP also had a heavy emphasis on aiding the development of state and local self-help and advocacy groups and facilitating dissemination of their ideas on a national basis. Through the years, the program promoted Learning Community Conferences to bring together researchers, service providers, family advocates, and primary consumers. CSP helps fund the annual Alternatives Conferences that bring together members of consumer organizations from all over the United States to pursue a national agenda. The CSP has probably been the major catalyst in helping develop services in which former psychiatric patients are staff employees or primary providers.

The CMHS funds three Consumer Technical Assistance Centers and two Consumer Supporter Technical Assistance Centers whose purpose is “to develop and implement activities that assist in the improvement of mental health service systems at the state and local levels (Substance Abuse and Mental Health Services Administration 2001). The National Mental Health Consumer Self-help Clearinghouse (NMHCSHC) in Philadelphia, under the direction of Joseph Rogers, encourages the development of consumer self-help groups and provides information, materials, and referrals on fundraising and program development. Organized in 1986, the NMHCSHC has worked to develop the infrastructure of consumer movements nationwide. They have helped build local and state self-help groups by providing technical assistance (TA) and disseminating information, developing consumer networks and coalitions, and generally building the capacity of consumer groups. The National Empowerment Center (NEC) in Lawrence, Massachusetts, directed by psychiatrist-consumer Daniel Fisher, similarly supplies TA to self-help groups. NEC has specific departments that focus on resource development and training conferences, consumer-run organizations, managed care and coalition building, information and referral, media relations, and training professionals on the consumer viewpoint.

Consumer Organization and Networking Technical Assistance Center (CONTAC), located in West Virginia, is the third consumer TA center funded by the CMHS. In collaboration with the other centers, CONTAC works nationwide to provide informational materials, on-site training and skill-building curricula, electronic and other communication capabilities, networking, and customized TA to build leadership and teach business management skills to local consumer groups.

In addition to the Consumer TA Centers, federal funding is received for two Consumer Supporter TA Centers. MHA has a grant to provide TA to consumer and consumer supporter organizations in areas such as education, advocacy, systems change, and coalition building, with a current focus on working with women who have experienced trauma. TA is provided in the form of research, training, information, and financial support. NAMI has the other Consumer Supporter grant. Their prior TA grant focused on implementing the evidence-based Wisconsin PACT program in service systems throughout the nation. The current STAR Center targets the promotion of cultural competence through knowledge dissemination, training, and on-site TA.

The Consumer/Survivor Mental Health Research and Policy Work Group was established in 1992 with support from the Mental Health Statistics Improvement Program and the Survey and Analysis Branch of the CMHS. The purpose was “to modify the relationships and dialogue between mental health professionals/service providers/policy administrators and consumers/survivors including fostering significant roles for consumers/survivors in all phases of mental health research, data standards development, planning, policy, and implementation of mental health services (Consumer/Survivor 1993, p 11).

A major focus of this work group was on outcome measures used in the CMHS-funded services research. A concept-mapping project resulted in a publication by NASMHPD titled Mapping Mental Health Outcomes from...
the Perspective of Mental Health Consumers (Trochim et al. 1993). This project generated recommendations to the mental health research community on outcome measures of greatest interest to consumers.

Service Development by Family and Consumer Groups

The 1999 Report of the Surgeon General (U.S. Department of Health and Human Services 1999) strongly recommended consumer participation in mental health services. For many years now, the CMH5 has been funding demonstration projects that required public mental health agencies to hire and train former patients to deliver services. They have also funded self-help agencies that are managed and staffed by former patients. According to Segal et al. (2002), these free-standing self-help agencies often serve as adjunct or referral sources for community mental centers, and, sometimes, represent alternative service sites.

For many years, NAMI groups in various localities developed resources to fill in gaps in their service delivery systems. Multiple housing facilities, employment opportunities ranging from thrift shops to furniture workshops, psychosocial rehabilitation programs, and even a psychiatric hospital are examples of resources developed throughout the United States. However, many NAMI members thought that families should be investing their energies in legislative advocacy rather than in service development. NAMI’s major mission is to augment and strengthen the service delivery system, such as encouraging the implementation of evidence-based practices, ensuring cultural competence and a focus on recovery, and offering an array of adequate services, including those required for jail diversion programs.

The consumer movements have had a different view of their role in services. Their focus is on using the experiences and skills of former psychiatric patients both within the system and as operators of consumer-run alternatives. Numerous CSP initiatives have been devoted to helping consumers achieve that end through funded model projects and inducements to the states. We have noted that as of 2002 there were reportedly at least 1133 consumer-run programs and enterprises. These have included housing and residential placement services, case management, peer companion programs, social centers, employment services including job training and consumer businesses, crisis respite houses, and special programs for homeless people. CSP-funded demonstration projects include a variety of consumer enterprises. Almost all states have networks of drop-in centers that provide socialization outlets outside of the traditional mental health system and, sometimes, fulfill an advocacy function as well. In many states, the sponsorship of consumer drop-in centers by state hospitals and community agencies is a common practice, typically with maximal independence offered to the consumer group.

Research Findings on Consumer Self-Help

Most of the early evaluations of therapeutic self-help groups tended to be qualitative or process research. Some studies of efficacy were inferred from the members’ satisfaction by use of normative data as a control condition. For example, a study of Recovery Inc. members, half of whom had been hospitalized for mental illness, focused on the benefits of membership to volunteer leaders of the organization. As a result of their participation, volunteer leaders gave high ratings to their overall satisfaction with life, health, work, leisure, and community. Their quality of life ratings were equivalent to the levels of satisfaction of a sample of the general public (Raiff 1982). A collaborative study of GROW by University of Illinois researchers compared members for 9 months or more with those who had been members 3 months or less. GROW members for the longer period were significantly better off in terms of larger social networks, a higher rate of employment, and lower levels of psychosis and depression (Rappaport et al. 1984). Another quantitative study looked at patients discharged from a state psychiatric hospital who participated in a Community Network Development self-help program. The research found that 10 months after discharge, participants required 50% less rehospitalization and two-thirds fewer inpatient days than a comparable group of nonparticipating patients (Gordon et al. 1982).

A study of four self-help groups for families of persons with mental illness showed in a time series analysis that the perceived helpfulness of the program for families was significantly related to the patients’ functioning in terms of fewer number of hospitalizations and fewer total days in hospital (Biegel and Yamatani 1986). The efficacy of the self-help sharing experience for family members has also received tangential empirical support from the work of McFarlane (2002) on psychoeducational interventions. His research found that interventions with multiple family groups were significantly superior to individual family interventions in deterring patients’ relapse, a finding attributed to the mutual support and information exchange of the group experience.

Family members and consumers have been increasingly involved in grand rounds, as lecturers in clinical training programs, and in training service providers. A randomized evaluation of consumer versus nonconsumer training of state mental health service providers found positive reactions to the use of consumers as trainers (Cook et al. 1993).

A process evaluation of six consumer-run drop-in centers in Michigan found that the centers were meeting their programmatic goals to provide acceptance, social support, and problem-solving help. The study found high levels of consumer satisfaction together with the participants’ reported feeling that they actually ran their centers (Mowbray et al. 1998). A 6-month survey of nine consumer-operated drop-in centers in Pennsylvania indicated a high level of client satisfaction (Kaufmann et al. 1993).

In California, the use of former patients as peer counselors on locked inpatient wards received enthusiastic evaluations from clinical staff, with most staff asking that the program be extended. The peer counselors reported personal benefits in terms of greater self-confidence, increased empathy, and feelings of being needed and responsible (McGill and Patterson 1990). A study of a Rehabilitation Services Administration training program for consumer case manager and human service worker aides, comparing team and individual approaches with intensive case management for frequent users of psychiatric hospitals, found significant advantages in consumer employment (Bond et al. 1991) Family members participating in a randomized trial of consumer versus nonconsumer case management teams reported equal satisfaction with the capabilities of consumer case managers (Mowbray et al. 1997).
A major question relates to job stress and the stability of former psychiatric patients as mental health service providers. A project in Denver, Colorado, trained consumers as case management aides in a psychiatric rehabilitation program. Of 25 trainees, 18 completed the program and 17 were employed as case management aides. At 2-year follow-up, the 15 trainees who were still employed had required a total of only 2 bed-days of psychiatric hospitalization (Sherman and Porter 1991).

Positive results were found in recent overviews of consumer-run services and CSP research demonstration projects based on consumer services. A comprehensive retrospective review of federally funded consumer/survivor-operated service programs in 13 states concluded that “Consumer/survivor-operated services are successful in increasing the overall quality of life, independence, employment, social supports, and education of consumer/survivors.” (Van Tosh and del Vecchio 2000, p. 79). This study found, moreover, that 70% of the federally funded initiatives were continued with other funding sources. The consumer recipients were objectively successful in capturing ongoing financial support, and, subjectively, they reported increased self-efficacy and self-esteem on standardized scales.

A multisite study by the CMHS found reduced symptoms, larger social networks, and enhanced quality of life when peer support was offered within traditional mental health services (Campbell et al. 2004). Prior research had indicated that peer support resulted in reduced hospitalization (Solomon and Draine 1995) and more effective case management (Felton et al. 1995). An overview of consumer programs by the International Association of Psychosocial Rehabilitation Services reported similar findings and stated that “Consumer service provision may be an essential feature of a support system devoted to recovery.” (Mowbray et al. 1997). A study of 255 long-term users of four self-help agencies found that “the significant ingredient promoting positive outcomes for clients of self-help agencies appears to be the provision of opportunities for clients to meaningfully participate in decisions about their care and the care of others in their organization (Segal and Silverman 2002).

Although consumers seem to be doing well on many of the evaluated programs, there are some negative or problematic findings as well. According to an evaluator for the CSP, consumer alternatives were never envisioned to serve as substitutes for mental health services; they were meant to empower consumers to gain some control over their lives. A qualitative analysis based on systematic observations of consumer-run services found that many consumer alternatives fell short of these empowering principles. Power conflicts and hierarchies developed in many programs. Consumers often tried unsuccessfully to replicate services provided by the local mental health clinic rather than to offer self-help alternatives (McLean 1994). The National Council for Community Behavioral Healthcare addressed some of these issues in a recently published handbook for providers on employing consumers in the mental health workforce (Townsend and Griffin 2006).

Relations of Professionals and Self-Help Groups
Many health and mental health professionals have welcomed the advent of the self-help movement. In a Workshop on Self-help and Public Health held by the Surgeon General’s Office of the Department of Health and Human Services, the major focus was on collaborative partnerships of professionals and self-help groups and a key recommendation that “exposure to the concepts and benefits of self-help should be included in the training curriculums of all helping professions.” (Surgeon General’s Workshop 1988, p. 32) The American Psychiatric Association’s Task Force on Treatments of Psychiatric Disorders views self-help groups as part of the therapeutic armamentarium. In their four-volume publication on treatment, Borman (1989) noted that self-help groups redefine pathological states, provide a shift in human service paradigms, promote and maintain competence, and reinforce positive mental health.

An increasing number of community mental health centers and rehabilitation facilities are welcoming support groups of patients and families, offering organizational help and free staff facilitators. Most professionally-run substance abuse programs include participation in AA or NA as a component of treatment. Newsletters for professionals and administrators often give information on self-help resources.

Under certain conditions, self-help groups may compose a parallel and sometimes competing system of care. Although most members simultaneously use clinical services, some may join self-help groups because of dissatisfaction with professional mental health treatment. A few self-help groups reduce the demand for clinical services because they offer alternatives and are hostile to the mental health system. Other groups, however, may raise awareness of deeper problems and provide referrals to preferred psychiatrists. Referrals work both ways and typically are mutually beneficial. Self-help group members learn about recommended professionals from their peers. Psychiatrists treating persons with a chronic mental illness are usually happy to learn about a local drop-in center to which they can refer their socially isolated patients.

Consumers who participate in self-help groups seem to be comfortable using dual systems of care. A Boston University study of six consumer-run self-help programs in various parts of the United States found that 50% of the self-help members were currently taking antipsychotic medication. Most also utilized professional mental health services such as counseling, day treatment, and inpatient care (Chamberlin et al. 1996). Drop-in centers whose funding comes from the state mental health system generally require that participants be under psychiatric care. Most self-help groups with seriously disabled members agree that they cannot deal with decompensation or other issues requiring clinical expertise.

Although concurrent psychiatric oversight is recommended, research suggests that self-help groups function best on their own without professional help in running the group. Emerick’s (1990) study of 104 self-help groups of psychiatric patients found that more than 70% reported little to no interaction with professionals. As previously indicated, only a third of these groups were considered to have a therapeutic orientation, and as might be expected, these were more amenable to professional alliances. A study of professional involvement with members of GROW, one of the therapeutic orientation models, compared social climate data and behavioral data among members of groups led by either a mental health professional (n = 36) or an indigenous
members' outcomes but significant differences in perceptions and behaviors. Members of groups led by professionals showed fewer agreements and self-disclosures, had less small talk and information giving, and rated their groups lower in cohesion and higher in leader control than did members of groups with indigenous leaders. The authors surmised that the professionals' more formal approach may have discouraged behaviors that they thought were less psychologically relevant and cautioned against professionalizing mutual help groups (Toro et al. 1998).

The picture is different on an individual basis, however. First-person accounts of consumers indicate numerous favorable recollections of their interactions with professionals (Hatfield and Lefley 1993). Many attribute the turning point of their recovery to a specific psychotherapist or to a rehabilitation specialist who helped them. Nevertheless, a number of former patients still tend to view negatively their overall experiences with the mental health system itself (Campbell 1989). In these cases, their negativity is typically related to feelings of disempowerment, external control, and loss of options for self-determination.

**Consumerism and a New Recovery Orientation in Mental Health Care**

Currently, there is strong emphasis on a recovery orientation in mental health services, strengthened by the recommendations in the President's New Freedom Commission on Mental Health Report (2003). These confirmed the vision of the director of Boston University's Center for Psychiatric Rehabilitation, who wrote almost a decade ago that recovery from mental illness was “the guiding vision of the mental health service system in the 1990s (Anthony 1993, p 7). In this vision, recovery is viewed as a subjective attitude change that enables one to live a life of meaning and purpose, even with the limitations imposed by mental illness. A consumer leader, director of a state network of drop-in centers, credited his psychiatrist with enabling him to fulfill the advocacy role that has shaped his recovery. He defined recovery as follows: "Recovery is not remission, nor is it a return to a pre-existing state... Recovery is the development of new ego and identity structures to replace those damaged by our illnesses... Recovery takes place through creation of new patterns of behavior that make our lives more satisfying and productive. People in recovery like themselves as they are, accept their disability, and enjoy the life they have. Acceptance of one's disability can lead to greater appreciation of one's own strengths and new levels of self-esteem." (Kersker 1994, p 337). In a qualitative analysis of personal accounts of the recovery process, Davidson (2003) lists a number of cogent elements. The first and, perhaps, the primary area is one of redefining self. The person eschews an encompassing label of “mental patient” and views the illness as only one aspect of a multidimensional self. Additional areas are: accepting illness; overcoming stigma; renewing hope and commitment; resuming control and responsibility; exercising citizenship; managing symptoms; being supported by others; and being involved in meaningful activities and expanded social roles.

Do peer-run services reinforce positive aspects of recovery, with a measurable therapeutic effect? A study of 1824 patients indicated that participation in a peer support program within the past 4 months showed a modest but significant association with recovery and empowerment factors such as confidence and hope, willingness to ask others for help, goal-orientation, self-esteem, self-efficacy, autonomy, optimism, and control over the future (Corrigan 2006).

**Conclusions**

The growth of the family and consumer movements has had a revolutionary impact not only on service delivery systems and funding resources but also on knowledge and practice. Like the National Society for Autistic Children before it, NAMI has helped change professionals’ attitudes toward families in numerous ways. By eliciting public statements and support from world-class researchers and authorities, and disseminating their information on the neurobiological substrates of major psychiatric disorders, NAMI has reinforced the changing ideas about familial roles in etiology among psychiatrists and other mental health professionals as well as the general public. The family movement has influenced clinical training curricula to provide state-of-the-art education, helped attain increased funding for basic research; and through advertising, television, and other media events, aided in accelerating the slow historical process of destigmatizing mental illness.

The advent of a powerful grassroots constituency has generated pronounced respect on the part of professional leaders and policymakers and an eagerness for political alliances. There has been consistent personal participation of American Psychiatric Association presidents and NIMH directors at all annual NAMI conferences. Many state psychiatric associations have urged their members to join NAMI as associate members. Clinical training programs have, sometimes, required their students to attend local NAMI meetings as part of their training, and some psychiatric residents have regularly attended as resource persons for NAMI family support groups (Lefley 1988).

Family members and consumers are increasingly involved on governance and advisory boards of service providers and on state mental health planning councils. In various departments of psychiatry, family members and consumers have lectured, given grand rounds, or made presentations at professional association meetings. They have also been encouraged to enter professional training programs through various governmental training initiatives.

The growth of the consumer movement has dramatically highlighted the heterogeneity of psychiatric patients. An unexpectedly high level of organizational skill and leadership is evident among many people with histories of psychiatric hospitalizations and diagnoses of major disorders. In mental health service delivery, some former psychiatric patients are apparently able to fulfill staff functions ranging from crisis intervention to case management, with the added therapeutic advantage of offering role models and experiential empathy to the patients receiving their services. Qualified consumers function as administrators in state mental health offices, directors of agencies, and principal investigators of grants.

The consumer movement itself has helped develop a wide range of skills and knowledge that are invaluable for psychiatric rehabilitation. These include writing, technical assistance, education in communications media, information dissemination, and decision-making skills. The political
advocacy process has brought empowerment, respect, and influence of important leadership figures to individuals who believe that their residual psychological deficits were related to powerlessness, marginality, and internalized stigmas (Campbell 1989). The job of helping one’s peers brings rewards of competence, altruism, and efficacy (Van Tosh and del Vecchio 2000). All of these would appear to be important factors in therapeutic growth.

Involvement in self-help and advocacy efforts seems to have additive therapeutic benefits, particularly for individuals adhering to a careful treatment regimen. These new developments are heuristic and warrant continuing research on the mechanisms of growth and paradigms of successful outcome in mental illness.

On a policy level, the primary consumer movement has had an impact both on state services and on rehabilitation ideology. Consumers have been particularly effective in promoting a recovery orientation in mental health services systems. Research shows that although there are concerns about the promises implicit in the recovery concept, the emphasis seems to be on persons living more positively with mental illness rather than presumptions of cure (Davidson et al. 2006). Cautions have been raised, however, about unrealistic expectations of persons with severe long-term mental illnesses. A group of consumer-professionals, writing in Psychiatric Services (Frese et al. 2001), have distinguished between categories of consumers with respect to the recovery vision. These authors note that advocacy for evidence-based practices, such as that offered by NAMI, is essential for the most seriously disabled consumers. Advocates who focus on consumer empowerment are those who are further along the road to recovery. These consumers merit increasing autonomy and input into the types of treatment and services they receive. The authors propose an integrative theory that maximizes the virtues and minimizes the weaknesses of each model. They also suggest that graduate and professional schools should be encouraged to recruit consumers in recovery for their training programs, both as teachers and as students. This way the programs will benefit from consumers’ experiential input and provide a scientific background for consumers to become knowledgeable mental health providers.

Consumerism is attractive to state and federal mental health authorities. This is demonstrated in the documents of NASMHPD, the allocations of funds by state program directors to support consumer-operated services, and the funding investments of the federal CMHS in developing the consumer movement. The influence of service-recipients was apparent in the Bush administration’s New Freedom Commission on Mental Health Report (2003), which called for a mental health system that is consumer and family driven. Nevertheless, there is a relatively small pool of qualified former patients who are capable of assuming meaningful roles in mental health agencies or in the development of alternative services. Consumer-operated programs for long-term patients are still a minor variable in the mental health service delivery systems of most states. These systems will clearly continue to require professionalism and, particularly, a psychiatric capability for all the foreseeable future. This need is acknowledged by the majority of patients and families. A consumer member of the NAMI board of directors described receiving almost 500 letters from consumers sharing their positive experiences with new medications and basing their hopes on continuing biological research (Beall 1994).

In an era of health care reform, an alliance of NAMI, MHA, interested consumer groups, and mental health professionals is essential for adequate coverage of mental health services. At the 1994 annual meeting of the National Association of Psychiatric Health Systems, the Psychiatric News reported the following message from former American Psychiatric Association president Paul Fink:

> Not too many years ago, patient advocacy was an unknown for most therapists or one they chose to ignore. … Now nobody “in their right mind” would make major policy decisions or testify before governmental bodies without including patients or their advocates in the process (Alliances 1994).

This alliance has been reinforced in successive meetings of psychiatrists and advocates. The Association of Community Psychiatrists has been involved for many years in open discussions with consumer groups. NAMI president Dr. Suzanne Vogel-Scibilia gave an invited address at the APA 58th Institute on Psychiatric Services in 2006, and APA President Pedro Ruiz has stated that one of his decisions is “to build additional bridges and cement the relationship between APA and NAMI….Partnering with NAMI strengthens our advocacy efforts” (Ruiz 2006, p 3). Professionals’ alliances with advocates, as well as peer support in service delivery where its benefits are shown to be evidence-based, appear to be the wave of the future in mental health systems.

Acknowledgment

The author thanks Paolo del Vecchio, Associate Director for Consumer Affairs, CMHS, for information on the consumer movement and current CMHS initiatives.

Pharmacological and Brain Stimulation Treatments
Introduction
Psychotropic medications are extensively used, with a recent survey indicating 7.2% of the general population taking at least one such medication (Beck et al. 2005). Nearly one in five community dwelling elderly (Aparasu et al. 2003) and 47% of nursing home residents (Snowdon et al. 2006) were found to be taking regular psychotropic medications, and 10% of adolescent office visits may result in the prescription of a psychotropic (Thomas et al. 2006). Prescribing physicians believe that they are equipped with knowledge of the primary actions of the drugs and the doses that need to be administered in order to treat psychiatric patients. Nonetheless, it is important to note the lack of diagnostic precision and pathophysiologic understanding of what in fact is being treated with medication. Psychotropic treatment is based on treating symptoms, which have a heterogeneous etiology. The strategy for drug discovery in psychiatry has relied on the serendipitous observation of the symptomatic benefit of a known drug, study of the putative mechanisms of that compound, and efforts to develop similar compounds with similar apparent mechanisms of action (Insel and Scolnick 2006). Moreover, it is important to appreciate the extensive variability in drug concentrations that occur in individual patients, given the same dose of a medication. As discussed below, there are a host of factors that will confound the individual patient’s actual exposure to a medication and thus contribute to variable therapeutic and adverse effects.

Newer approaches to drug development include development predicated on understanding the pathophysiological properties of illness (Lewis and Gonzalez-Burgos 2006) and based on population pharmacokinetics (PK) to model dosing (Bigos et al. 2006) as well as innovations in clinical trial design (Roose and Schatzberg 2005). Regardless of when these innovations will impact the pharmacopeia and evidence base, clinicians need to incorporate general clinical pharmacological principles when treating the patients who are suffering now.

Pharmacokinetics
Pharmacokinetics is a description of how drug concentrations change with time and ultimately describes the relationship between a given dose and plasma concentration. More simply, PK describes what the body does to the drug. A pharmacokinetic study describes these concentration changes and is classically performed using a small number of subjects given a single dose of medication followed by multiple blood samples. These studies provide information on absorption, bioavailability, distribution, metabolism, steady state, and elimination—factors that will be addressed here. This section will also address the growing field of population PK and the effects of aging on the above. See Figure 99–1 and Table 99–1.

Absorption/Formulation
The formulation of a drug and its route of administration are significant factors involved in the dose–concentration relationship. These factors contribute to variabilities in the system and can determine the onset of actions of administered medications.

Intravenous (IV) administration is the fastest and easiest route of administration to control medication exposure, given the absence of the first-pass effect (see below). However, it is almost never encountered in psychiatry. More common is the intramuscular (IM) formulation, especially in the treatment of agitated behavior and in the face of nonadherence. Benzodiazepines (such as lorazepam)
and antipsychotics (both in short-acting and in depot formulations) are often given this way. IM antipsychotics can be typical (e.g., haloperidol and loxapine) or atypical (e.g., risperidone and ziprasidone). At present, the only long-acting IM atypical antipsychotic is risperidone.

Most commonly used is oral (p.o.) administration, the utility of which is conferred by the highly lipophilic nature of central nervous system (CNS) medications. Formulation is a major factor involved in the rate of p.o. absorption. Whereas rapidly dissolving oral wafers (e.g., olanzapine wafer and risperidone M-tab), as well as solutions, suspensions, and sublingual formulations can be absorbed quickly, coatings and capsules with differential release technologies (e.g., bupropion XL and methylphenidate OROS formulation) as well as transdermal patches (nicotine) can delay absorption of medications. These changes in absorption can confer single daily dosing onto a medication or provide variation on classic PK profiles. The rate of absorption can affect peak plasma levels with slow absorption having lower peak levels than those with fast absorption. By minimizing the effects of peaks far above the minimum effective concentration (MEC) and troughs far below the MEC from immediate release formulations, slow release formulations can minimize peak-associated side effects and trough-related lack of efficacy. They may allow therapeutic action overnight and potentially improve adherence as well.

Oral drugs are absorbed via passive diffusion across the intestine, although some are absorbed via facilitated diffusion or active transport across gastrointestinal (GI) membranes via P-glycoprotein. Passive transport occurs as the drug diffuses down a concentration gradient and is driven by the magnitude of the concentration gradient. Most psychotropics are well absorbed from the GI tract with an onset of 30–45 minutes and full absorption within 2–3 hours. Anticholinergic medications can decrease intestinal motility and delay the rate of absorption. Antacids can delay the absorption of medications by altering their ionization and delaying gastric emptying time, and high-fiber supplements or cholestyramine can do this as well.

**First Pass/Bioavailability**

In transition from the GI tract to the systemic circulation, many drugs are metabolized as they pass through the GI membranes and hepatic circulation. This is known as the first-pass effect (Burton et al. 2002). Cytochrome P 450 3A4 (CYP3A4) is predominantly responsible for first-pass metabolism both in the small intestinal lumen and in the liver (Kolars et al. 1992). P-glycoprotein is involved in first-pass effect as well. P-glycoprotein causes an ATP-dependent active transport efflux of various drugs from cells and is present in small intestine and kidney, as well as the blood–brain barrier (BBB) and is subject to genetic variation in functioning (Benet et al. 1999, Doherty and Charman 2002).

The term bioavailability is used to describe the fraction of an administered dose of medication that reaches the systemic circulation. Bioavailability depends on the amount of drug absorbed through the GI mucosa and remains unaltered by the first-pass mechanisms of the liver, irrespective of the rate or amount of absorption. Thus, some active drug is metabolized and rendered unavailable to act at the effect site. If the first-pass hepatic clearance for a drug is extensive, bioavailability will be low. Although unmetabolized drug generally provides the desired effect, some drugs such as codeine are prodrugs, which are transformed into active metabolites to produce the therapeutic effect.

With aging, gastric acid secretion decreases and drugs that require an acidic environment to be ionized can be affected (e.g., ketoconazole and iron) (Iber et al. 1994). Decreased blood flow may also decrease first-pass metabolism, thus increasing bioavailability (McLean and Le Couteur 2004).

**Distribution**

As drugs are administered and absorbed they are distributed to tissues, and this is dependent on circulation

**Excretion**

| • Decreased renal clearance |
and membrane permeability. Well-perfused tissues such as liver, kidney, and brain receive most of the drug initially, while distribution to muscle, fat, and skin is slower, delaying equilibrium between peripheral tissue concentration and that of the blood. A two-compartment mathematical model describes the distribution of drugs to tissue—a central compartment of circulation and rapidly distributed tissues, followed by equilibration in the peripheral compartment of less accessible tissues (Gibaldi and Perrier 1975). Plasma drug concentration decreases with distribution to tissues, and it is only unbound drug that is able to cross into tissue. The volume of distribution (\(V_D\)) is a measure of the apparent space in the body into which a drug distributes, that is, the volume in which the amount of drug would need to be uniformly distributed in to produce the observed blood concentration. \(V_D\) is not a real volume but rather a reflection of how a drug will distribute throughout the body. For lipophilic drugs, the \(V_D\) describes the size of the reservoir of fatty tissues, and, for water-soluble drugs, it describes the total body water. It is expressed by the following formula:

\[
V_D = \frac{\text{total amount of drug in the body}}{\text{drug blood concentration}}
\]

Factors affecting distribution include lipid solubility of the drug, the permeability of the BBB, and plasma protein binding. Highly lipophilic drugs can be distributed more widely than those that are not. As the BBB is a lipid membrane, increasing lipid solubility confers a faster onset of action due to increased permeability through the membrane. Also, P-glycoprotein is present in the BBB and may affect distribution of drug (Benet et al. 1999). Plasma protein binding affects distribution as only unbound drug can be redistributed to tissues. Drugs bind to plasma albumin and \(\alpha_1\) acid glycoprotein. Protein binding may decrease drug distribution, as bound drug stays in the blood stream and only free drug equilibrates outside the bloodstream. Only the free fraction of drug exerts a pharmacologic effect and undergoes hepatic metabolism or renal filtration. Although changes in protein levels can theoretically affect distribution, these are now thought to be less clinically relevant than before except in rare cases of drugs with a high extraction ratio and narrow therapeutic index that is given parenterally (Benet and Hoener 2002). However, changes in protein binding may affect interpretation of drug levels, which typically measure total drug, as opposed to bound or unbound portions.

With aging, body water decreases by 10–15% and body fat increases by 20–40% (Beaufreere and Morio 2000). Water-soluble drugs will have a decreased volume of distribution, increased plasma concentration, and, thus, an increased potential for toxicity. Examples of this include lithium and digoxin. For lipid-soluble drugs (as most psychotropics are), this will result in an increased volume of distribution and therefore a longer half-life, leading to drug accumulation. Protein composition changes with age as albumin decreases and \(\alpha_1\) acid glycoprotein increases, but mentioned, this is not likely clinically significant. The BBB also changes with age such that permeability increases with increasing age (Pakulski et al. 2000).

**Metabolism**

Drug metabolism occurs via two phases, I and II. Phase I involves primarily oxidation reactions including dealkylation, hydroxylation, oxidation, deamination, desulfuration, and sulfoxide formation and is mediated by the cytochrome P450 (CYP450) system. Phase II metabolism involves conjugation or synthetic reactions that render the molecule more water soluble and hence available for renal excretion.

The CYP450 system is a generic name describing a superfamily of oxidative enzymes important in plant, animal, and human physiology. They metabolize not only endogenous compounds but also xenobiotics including environmental compounds and drugs (Nemeroff et al. 1996). This superfamily contains over 30 related enzymes, and five human CYP450 proteins metabolize more than 90% of drugs used today. These include CYP 1A2, 2D6, 2C9, 2C19, and 3A4. CYP450 enzymes are found primarily in the liver but also in the GI tract, kidney, and lung. Tables 99–2 through 99–6 list the common substrates for these enzymes. An up-to-date website highlighting the CYP450 system can be found at http://medicine.iupui.edu/flockhart/table.htm (Flockhart).

Pharmacokinetic drug interactions are well described and result from one drug affecting the metabolism of another. Substrate drugs or xenobiotics for CYP450 can be inducers (increasing enzyme activity) or inhibitors (decreasing enzyme activity) of various CYP450 isoenzymes. Competitive or noncompetitive inhibition by one drug on the relevant hepatic enzyme can result in slowed or decreased metabolism of another drug metabolized by the same enzyme. The increase in plasma concentration of the affected drug is immediate, and this second drug reaches a new steady state. For example, giving fluvoxamine to a patient already taking clomipramine will result in increased clomipramine levels. This occurs because of inhibition of clomipramine demethylation via CYP2C19 by the added agent. If the new

steady state for the affected drug is too high, toxicity can ensue (see Clinical Vignettes 1 and 2 for further discussion). Conversely, induction requires synthesis of CYP isoenzymes, and this effect may not be immediately apparent. Once the CYP450 isoenzyme is produced, plasma levels of the affected drug will decrease accordingly. Examples include the induction of CYP3A4 by carbamazepine, which then increases metabolism of oral contraceptives, decreasing their effect. This is especially true if a drug is highly toxic or has a narrow therapeutic window (see Table 99–3).

Variability in the CYP450 system exists due to genetic polymorphisms in coding genes. Differences in copy number, activity, or substrate affinity of the isoenzymes can result in enzymes with inactive, decreased, normal, or increased activity (Ingelman-Sundberg et al. 1999). These interindividual and interethnic differences can result in variable response to drugs.

### Clinical Vignette 1

A 28-year-old man with schizophrenia was admitted with a relapse of his psychosis. He was last well approximately 6 weeks ago when he started hearing voices and feeling like people were watching him. This was similar to his first episode of illness. He deteriorated to the point that he was agitated and started walking around with a knife. He became acutely paranoid and pulled the knife on a bystander. The police were called and he was brought to the hospital. He was stabilized on the inpatient unit with a combination of olanzapine 15 mg p.o. qhs and over the next 2 weeks his auditory hallucinations resolved and his paranoia diminished. He was discharged home at that time with follow-up in clinic. Four weeks later, there was an urgent phone call from his parents stating that he was once again psychotic. They insist that he had been taking his medications. Of note is the fact that he had been smoking many cigarettes since his discharge.

**Discussion:**
The patient was stabilized in hospital in a nonsmoking unit, although he did smoke a little toward the end of his hospitalization when he went on passes. Upon discharge, he resumed his previous smoking regime, which induced CYP1A2 metabolism. With increased activity of this isoenzyme, there was increased metabolism of olanzapine, which then decreased to subtherapeutic concentrations resulting in relapse. This is an example of a pharmacokinetic drug interaction often seen in clinical practice.

or inhibitor is suddenly discontinued, or if there is a sudden change in clinical picture.

Variability in the CYP450 system exists due to genetic polymorphisms in coding genes. Differences in copy number, activity, or substrate affinity of the isoenzymes can result in enzymes with inactive, decreased, normal, or increased activity (Ingelman-Sundberg et al. 1999). These interindividual and interethnic differences can result in variable response to drugs.

### Clinical Vignette 2

A 76-year-old woman with dementia is stable in long-term care on a regime of quetiapine 50 mg bid, alprazolam 1 mg bid, and donepezil 10 mg qd. She visited a different floor in the nursing home and after a few days is noted to be listless, less interested in socializing, and more sedated. She was noticed to be drinking quite a bit of grapefruit juice, which was freely available on this unit. After several days, she is diagnosed with depression and treated with fluoxetine 10 mg p.o. qd. Two days later, she becomes excessively sedated such that her drive to breathe is decreased and she is difficult to rouse. She is sent to hospital.

**Discussion:**
In this case, the addition of grapefruit juice results in inhibition of CYP3A4, which metabolizes both alprazolam and quetiapine. Increasing blood levels of those drugs results in sedation and listlessness, which is diagnosed as depression. The addition of fluoxetine complicates matters as it further inhibits CYP3A4 through its active metabolite norfluoxetine, resulting in a complex pharmacokinetic drug interaction and hospitalization of this patient.

The most studied genetic polymorphism affecting drug metabolism is that of CYP2D6, where the poor metabolizer status is an autosomal-recessive trait. Null mutations on this gene result in impaired CYP2D6 activity. Clinically, this can manifest in drug toxicity. For example, when perphenazine was given to poorly metabolizing elders, extrapyramidal symptoms were exaggerated (Pollock et al. 1995). Conversely, 4% of Caucasians are ultrarapid metabolizers due to increased CYP2D6 activity. Ultrarapid metabolizers are often misdiagnosed as treatment resistant due to poor response. They frequently require higher than expected doses of CYP2D6 drugs and therapeutic blood monitoring (especially for tricyclic antidepressants) may be helpful in treating these patients. Thus far, over 100 allelic variants have been identified in the CYP2D6 system, contributing to the broad variability in metabolism via this isoenzyme (Ingelman-Sundberg et al. 2007) some of which are shown in Table 99–7.

With aging, there appears to be no uniform decline in liver metabolism by the CYP450 system (Pollock et al. 1992b, Schmucker 2001). However, it is possible that functioning of CYP2C19 may decline with age (Bebia et al. 2004). For example, citalopram’s clearance is reduced in older patients (Bies et al. 2004), and this may be in part due to decreased CYP2C19 function. Reductions in both hepatic blood flow and hepatic mass place greater emphasis on interindividual differences in the metabolic capacity of the elderly (Wynne et al. 1990). Drugs metabolized by CYP3A4, such as alprazolam, triazolam, sertraline, and nefazodone, appear to be cleared less well in elderly patients (Greenblatt et al. 1991, Ronfeld et al. 1997, Timmer et al. 1997). However, this may also be because metabolism of some CYP3A4 drugs is perfusion limited and thus decreased in the elderly. Liver disease can also modulate CYP450-mediated metabolism (Frye et al. 2006) but not equally across isoenzymes, suggesting sequential progressive model of hepatic dysfunction.

### Elimination/Excretion

After conversion to hydrophilic metabolites, drugs are eliminated from the body by renal excretion via the processes of glomerular filtration, active tubular secretion, and passive tubular reabsorption. Clearance (Cl) is defined as the volume of blood from which drug is removed per unit time. Clearance is described by the following equation, which is analogous to the Michaelis–Menten equation for enzyme kinetics (Gibaldi and Perrier 1975):

$$ Cl = \frac{v_{in}}{K_m + C} $$

where $K_m$, the Michaelis–Menten constant, represents the concentration at which half the maximal rate of elimination is reached, $C$ is plasma concentration of drug, and $v_{in}$ is equal to the maximal rate of elimination. Clearance does not indicate how much drug is being removed but rather the volume of blood or plasma from which drug would have to be removed completely to account for the clearance. From a clinical perspective, creatinine clearance (CrCl) is used to estimate the clearance of drugs and can be calculated by the Cockcroft–Gault equation (Cockcroft and Gault 1976):

$$ CrCl (\text{ml/min}) = \left(140 - \text{age}\right) \times \left(\text{body wt (kg)}\times 0.85 \text{ if female}\right)/\left(72 \times sCr \text{ (mg/dl)}\right) $$

where $sCr$ is serum creatinine.

Half-life ($T_{1/2}$) of a drug is the time required to decrease concentration by 50%, and this determines the rate of drug accumulation in the body. Half-life can be expressed by the following formula:

$$ T_{1/2} = \left(V_D/\text{Cl}\right) \times 0.693 $$

Increased $V_D$ (volume of distribution) and decreased Cl (clearance) can increase $T_{1/2}$, leading to drug accumulation. Different drugs have different types of elimination kinetics. First-order or linear kinetics occur when the amount of drug eliminated over time varies with the amount available for elimination, that is, it is proportional to dose. Most psychotropics are eliminated this way. Zero-order kinetics occurs when fixed amount of drug removed per unit time. Due to rapid saturation of elimination mechanisms, drug metabolism is constant. Alcohol is the classic example of zero-order elimination. Intermediate kinetics occurs between the zero and first order. At low doses drug metabolism is first order and then saturates at high doses becoming zero order.

With aging, there is a well-established decline in glomerular filtration rate (GFR). This change in clearance varies and can be exacerbated by concomitant illness (diabetes and hypertension) and concurrent medications (nonsteroidal anti-inflammatory agents) (Pollock et al. 1992b). Accumulation of active metabolites can be a significant clinical concern, as is the case with tricyclic antidepressants (Pollock et al. 1992a). Diminished renal clearance will result in accumulation of water-soluble drugs (lithium and digoxin) and active metabolites of some medications (e.g., risperidone and venlafaxine).

### Steady State

After a single dose of a drug there is an initial rise to a peak plasma level, after which concentration falls until the drug is
completely eliminated from the plasma. The concentration below which no drug effect is seen is termed the minimal effective concentration (MEC). The MEC defines the lower limit of the therapeutic window, the upper limit of which is defined by the concentration at which the drug produces toxicity. Drugs that have a wider therapeutic window are safer and less prone to serious pharmacokinetic interactions. As drugs are given in multiple dosing, concentration rises to reach steady state. Steady state is when the amount of drug entering the body equals the amount of drug leaving the body. This level occurs after approximately 4–5 half-lives of the drug and is described by the following equation (Gibaldi and Perrier 1975):

\[ C_{ss} = \left(1.44 \times D \times T_{1/2}\right)/V_D \times Di \]

where \( C_{ss} \) is the average steady-state plasma level, \( D \) is the absorbed dose, \( T_{1/2} \) is the elimination half-life, \( V_D \) is the volume of distribution, and \( Di \) is the dosing interval.

Steady states achieved with multiple dosing result in peaks and troughs in the plasma concentration. Dose, interval, and formulation determine these peaks and troughs. In general, decreased frequency of administration results in increased peak-to-trough differences. The ratio of the peak-to-trough plasma concentration is known as the fluctuation index, and extended release formulations can result in a decreased fluctuation index.

**Population PK**

Classical PK studies involve multiple samples from carefully selected volunteer subjects and generate PK models that are then generalized to other populations such as the elderly. Although helpful, they do not capture the subtlety of PK changes, nor can they identify unexpected factors influencing PK. For example, the unexpected interaction between ketoconazole and terfenadine resulted in fatal toxicity and removal of terfenadine from the market (Dresser et al. 2000).

Population PK developed as a way to identify unexpected influences of drug PK (Ette and Williams 2004) and to characterize and model sources of variability in drug concentration. Population PK involves studying large numbers of people in minimally invasive ways. It models drug concentration by looking at the central tendency of a PK parameter across an entire population and assesses inter- (between subject) and intra-individual (within subject) differences in drug concentration. Population PK thus identifies factors that contribute to pharmacokinetic and pharmacodynamic variability using the concept of mixed effects models (i.e., fixed + random). Fixed effects include parameters such as clearance and volume of distribution, as well as covariates such as age, weight, sex, and ethnicity. Random effects include variability, both intra- and inter-individual. Every data point from all individuals contributes to the identification of sources of variability (Bigos et al. 2006). A recent population pharmacokinetic study with paroxetine in elderly subjects with major depression involved 171 subjects and a total of 1970 paroxetine concentrations. A nonlinear mixed-effects model was developed for these subjects and demonstrated that a two-compartment nonlinear PK model best described the data. Weight and CYP2D6 polymorphisms influenced maximum velocity of metabolism, and gender had an effect on volume of distribution of the central compartment. The results showed that weight, gender, and genotype contributed to variability in PK parameters and suggested that dosing should vary according to these parameters (Feng et al. 2006).

**Pharmacodynamics**

PD addresses the time course and intensity of drug effects on the body or what the drug does to the body. Variability in PD can exceed that of PK such that similar plasma concentrations can produce different pharmacological effects in different patients. This section will discuss the drug–receptor concept, dose–effect relationships, metabolism and its variability, and pharmacodynamic drug interactions. The role of kinetic–dynamic (KD) modeling in clinical pharmacology will also be reviewed.

**Drug–Receptor Concept**

The pharmacological effects of most drugs derive from their interaction with a receptor, which then modulates the intrinsic physiology of the organism. If the drug emulates or enhances the function of the endogenous ligand, it is called an agonist. Conversely, if by binding the receptor a drug blocks function at that receptor, it is called an antagonist. Partial agonists are active at the receptor, but to a lesser extent than the endogenous ligand. Beneficial effects of medications often come from activity at target receptors, and side effects often arise from activity at other receptors. For example, the atypical antipsychotics may gain their efficacy from antagonism at both the serotonin 2A (5HT2A) and the dopamine 2 receptors (DRD2). Antagonism at histaminergic 1 (H1) and muscarinic receptors results in sedation, weight gain, constipation, urinary retention, dry mouth, and cognitive impairment. Antagonism at the α1 adrenergic receptor may cause orthostatic hypotension. Benzodiazepines are examples of GABA agonists, and memantine has partial antagonist activity at NMDA-operated cation channels. Aripiprazole is a partial agonist on the dopamine system where antagonistic effects occur in areas of high dopamine activation and agonism at sites of low dopamine activation, resulting in fewer adverse hormonal or motor events (Ohlsen and Pilowsky 2005).

Drug–receptor interactions may be saturable, selective, and reversible. Saturability implies that increasing the dose or concentration of the drug will no longer increase the effect due to maximum binding and rate of receptor activity. Selectivity of a receptor describes its high affinity for the drug over other compounds, but increasing concentration can result in decreased selectivity. Binding at the receptor can be reversible or irreversible depending on the nature of the bonds (i.e., covalent or ionic). Most psychotropics bind reversibly with receptors.

**Dose or Concentration–Effect Relationships**

If a drug has physiological activity, there has to be a relationship between its concentration at its effector site and its actions. The nature of this relationship may be hard to assess. Nonetheless, understanding the concept of
concentration–response as it relates to a specific drug can help with treatment. For example, the sigmoid concentration–response curve is the most common description of how concentration and response are related. On the flat, initial part of the curve, concentration increases result in minimal therapeutic effects. The most direct relationship between increasing concentration and increasing effect is on the linear part of the curve. Maximal efficacy is reflected in the flat, terminal part of the curve. The shape of the curve is specific to an individual and is a source of pharmacodynamic variability. Even within individuals, the shape of the curve can change, depending on comorbid medical illness. If there exists drug toxicity, a parallel sigmoid curve exists delineating the toxic effects. The therapeutic window in this case is defined as the difference in concentration between effective and toxic doses. For example, tricyclic antidepressants have a therapeutic window, above which cardiotoxicity can occur. With aging, the therapeutic window can be narrower, as the elderly are more sensitive to the adverse effects of psychotropics at lower concentrations (Pollock 1999). The concentration–response curve can shift to the left, resulting in toxicity at lower doses. Physiological factors such as orthostatic control of blood pressure, water balance, postural control, and thermoregulation can be less robust in the aged, resulting in greater difficulty-tolerating medications. For example, SSRIs are more likely to result in syndrome of inappropriate antidiuretic hormone secretion and fragility fractures in the elderly (Kirby and Ames 2001, Richards et al. 2007). The existence of a therapeutic window for older medications gave rise to the practice of therapeutic drug monitoring (TDM), but a lack of information on concentration–effect relationships of newer psychoactive medications has resulted in less frequent use of this technique. Also, newer medications with wider therapeutic windows are dosed on the flat part of the curve. Currently, in light of better understanding of the large interindividual pharmacokinetic variability for virtually all psychoactive drugs, and worse clinical efficacy in inadequate and excessively high concentrations, an argument can be made for resuming this practice. A TDM “nouveu” model advocates for modeling both inter- and intraindividual PK variation over time in order to optimize dose. The therapeutic “window” should be used as a guiding principle rather than an absolute reference value (Bengtsson 2004).

Pharmacodynamic Drug Interactions
More difficult to elucidate than pharmacokinetic drug interactions, pharmacodynamic drug interactions occur due to alteration of the clinical effects of a drug by another drug at the same receptor site. For example, concurrent use of alcohol and benzodiazepines can result in exacerbation of psychomotor impairment due to additive effects at the same GABA receptor. Similarly, addition of SSRIs and MAOIs can result in serotonin syndrome. Anticholinergic toxicity is a common example of pharmacodynamic drug interactions in the elderly. Many common drugs may have modest anticholinergic effects, and these are cumulative (Tune 2000). An assay may quantify serum anticholinergic activity in order to assess and minimize this serious pharmacodynamic interaction but currently is only available in research settings (Carnahan et al. 2002, 2006) (Clinical Vignettes 3 and 4 highlight this area further).

Clinical Vignette 3
A 70-year-old woman is living at home. She is taking ranitidine for esophageal reflux and oxybutynin for urinary incontinence. She develops mild depression with sleep disturbance and starts taking OTC antihistaminergic sleep agents to help her with initial insomnia. She becomes more anxious and her sleep worsens. She starts getting confused, presents to her primary care provider who queries dementia as she is starting to get lost. She is prescribed alprazolam as a hypnotic and she gets more confused as her cognition worsens. She goes again to the primary care provider who diagnoses dementia and starts her on donepezil. Her reflux worsens, and she stops eating. Her mood worsens, and she becomes dehydrated, resulting in delirium with symptoms of disorientation and hallucinations. She is brought by emergency medical services (EMS) to the emergency room and is admitted to hospital.

Discussion:
This is an example of the cumulative anticholinergic effect of multiple medications. OTC sleep aids that are potent anticholinergic, as well as other medications that are not always recognized as being anticholinergic, result in a pharmacodynamic drug interaction. The potent benzodiazepine alprazolam will also contribute to further confusion, and, being short acting, it may not be effective as a hypnotic. The prescription of donepezil, which is cholinomimetic, may counter some of the anticholinergicity of the other medications but has its own side-effect burden including procholinergic effects on the GI system. The GI disturbance is iatrogenic and contributes to her overall morbidity.

Clinical Vignette 4
A 55-year-old man with a previous vascular history is taking warfarin for anticoagulation. He has a family history of depression and has had two previous episodes at the ages of 24 and 38 years, successfully treated with fluoxetine. Due to the previous response he is started on fluoxetine again. Within 2 days his prothrombin time international normalized ratio (PT INR) is elevated and he has a cerebral bleed.

Discussion:
This is an example of a complex drug interaction involving both pharmacokinetic and pharmacodynamic mechanisms. Warfarin's two enantiomers are metabolized differently: more biologically active S-warfarin is metabolized by CYP2C9 while R-warfarin is mainly metabolized by CYP1A2. Inhibition of CYP2C9 by fluoxetine results in increased warfarin activity and increased PT INR. Further, platelet activity is depressed by SSRIs due to serotoninergic activity on platelets (Pollock et al. 2000), and this is reflected in prolonged bleeding times. Thus, by two mechanisms, this patient is at risk of a bleed with the addition of fluoxetine to warfarin.

Genetic Components of Variability
Studying the genetic contribution to the variability in drug response is the cornerstone of pharmacogenetics (Kalow et al. 1986) and historically this has involved single gene variations in metabolism of medications. The study of single nucleotide polymorphisms (SNPs) has led us to the
understanding that 20% of Chinese and 7% of Caucasians are deficient in functional activity of the CYPs 2C19 and 2D6, respectively (Preskorn 2006). Pharmacogenomics addresses multigenic controls of drug variability (Grant 1999) and aspires toward treatment individualization. Genetic differences may affect every aspect of pharmacokinetic and pharmacodynamic processes.

The clinical significance of genetic variability depends on the drug and the type of variability. In terms of metabolism, poor metabolizers are at risk of toxicity for drugs that are inactivated by the CYP isoenzyme in question and have a narrow therapeutic index (Pollock et al. 1992a). Conversely, drugs with a wider therapeutic window may be of less clinical concern. In a study of 46 elderly patients receiving venlafaxine-XR, CYP2D6 genotype and steady-state plasma levels of venlafaxine (VEN) and o-desmethylvenlafaxine (ODV—the active metabolite) were determined. Although VEN concentration per unit dose was significantly higher and ODV concentration per unit dose was significantly lower in participants who carried intermediate or poor 2D6 metabolizer status, CYP2D6 genotype was not associated with medication-associated side effects (Whyte et al. 2006). Conversely, poor metabolizers would have a low conversion rate of a prodrug, like codeine, to an active metabolite, thus resulting in an inadequate therapeutic response.

Receptors and drug transporters are also targets for pharmacodynamic variability. Dopamine 3 receptor (DRD3) polymorphisms have been shown to play a role in medication-induced movement disorders. An Ser9Gly polymorphism in the N-terminal extracellular domain of this receptor is associated with an increased rate of tardive dyskinesia in patients treated with typical antipsychotics (Basile et al. 1999). Presence of the Taq1A A1 allele of the DRD2 and the nine repeat allele of the dopamine transporter (DAT1) variable number of tandem repeats polymorphism might be at risk factors for EPS caused by antipsychotic drugs in schizophrenia (Guzey et al. 2007), as may polymorphisms of the 5HT 2A and 2C receptors (Gunes et al. 2007). Another recent example found butyrylcholinesterase (BuChE) genotype may influence the response to rivastigmine (Blesa et al. 2006).

**KD Modeling**

Whereas PK addresses the relationship between time course of a drug and its attendant body concentration, PD addresses the relationship between time course and drug effects on the body. Pharmacodynamic differences are difficult to interpret without concentration data, and thus combining PK and PD to address the relationship between concentration and effect is the charge of KD modeling. A KD study involves assessing both drug concentration and drug effect at multiple times after dosing in laboratory conditions. The effect measurement can be subjective, semioobjective, or objective and can depend on the drug under study. Subjective measurements can involve assessment of mood or anxiety, semiojective measurements can involve speed or motor performance, and objective measurements can involve evoked response potentials or neuroimaging. Various models can describe the concentration–effect relationship including linear, exponential, and sigmoid, in increasing complexity. The model can generate effect measures such as EC50 (the concentration that produces 50% effect) and E_max (concentration that produces maximal effect) having implications for dosing regimes. Difficulties arise when the wrong model is applied or when peripheral drug concentrations are not representative of effect site concentrations (Greenblatt and Harmatz 1993).

By assessing concentration and accounting for variability in exposure to medication, the power and interpretation of pharmacogenetic, neuroimaging, and clinical studies should improve, with fewer subjects needed to improve this power (Lotrich et al. 2006). Poor correlations between peripheral and central concentration measurements can be a source of error in the model. For example, differences in P-glycoprotein transport activity can account for differential entry of medications into the brain, and this has been demonstrated via positron emission tomography (PET) (Sasonko et al. 2005).

**Safety and Efficacy**

A prescribing physician must balance the two fundamental areas of safety and efficacy when it comes to choosing a medication. Although some safety issues are evident in initial clinical trials, others become apparent after marketing and extensive prescriber experience with the medication. Of new molecular entities approved by the FDA from 1980 to 1999, 21% underwent a labeling change for the original indication and patient population. Of those medications, 80% of the changes represented a dosing reduction (Peck 2003). In special populations, dosing is an even greater issue. Package inserts (PIs) for oral medications often do not contain dosing information for older patients, with only 28% of PIs for the most commonly prescribed drugs in the elderly having specific dosing recommendations (Steinmetz et al. 2005). Further, 66% of admissions to an acute geriatric medical unit were preceded by at least one inappropriate medication, and of those patients taking appropriate medications, adverse drug reactions (ADRs) had a prevalence of 16.4% (Laroche et al. 2007). We have discussed many of the factors that contribute to variability in a patient’s exposure to a medication, and awareness of these factors may assist in prescribing. Knowledge of these factors is important since greater variability may result in greater risk of toxicity.

**Compliance/Adherence**

An often overlooked component of variability in the dose–effect relationship is compliance. Whether by commission, omission, or confusion, patients often miss medications or take them inappropriately. In psychiatry, many illness states can result in nonadherence; paranoia from psychosis, denial in mania, or confusion in dementia can all result in missed medications or medication errors. Providers may attribute lack of treatment response to treatment resistance when adherence may be the issue. It is important to consider this when reassessing the efficacy and safety of a medication and to try to verify adherence when considering dosing changes. Caregivers can be asked to provide information, and drug levels may at least help to determine the presence or absence of prescribed medications. Nonadherence has significant clinical consequences. A California Medicaid study estimated adherence by prescription refills in a population of patients with schizophrenia. Rehospitalization rates correlated with increasing medication gaps, highlighting the clinical significance of both nonadherence and partial adherence (Weiden et al. 2004).
Adverse Drug Events/Reactions

ADRs are unintentional, unexpected, or undesired medication responses that result in clinically significant outcomes such as admission to hospital, a change in medication regime, morbidity, or mortality. As more psychotropics are prescribed, ADRs increase in their incidence. A recent study quantified adverse events in a high-risk multimorbid population of nursing home residents with Alzheimer’s disease and psychosis (Oliveria et al. 2006). Of 7728 residents studied over 2 years, at least 90% had psychiatric comorbidity, and the most common adverse event was accidental injury occurring at a rate of 97.7 per 100 person years. This study of high-risk patients highlights how pharmacokinetic and/or pharmacodynamic interactions can result in ADRs. Another potential cause of ADRs is medication error. A review of 5366 medication errors from 1993 to 1998 found 469 to be fatal. Of those, 48.6% occurred in patients over 60 years. The most common types of errors resulting in patient death involved administering an improper dose (40.9%), administering the wrong drug (16%), and using the wrong route of administration (9.5%) (Phillips et al. 2001). The Institute of Medicine (IOM) issued a report “To Err Is Human: Building a Safer Health System” in 1999 and a follow-up report in 2005, addressing systemic ways to decrease medical errors. By recommending a specific reporting system, the IOM has highlighted the importance of awareness on medical errors and the systematic evaluation of these errors (Leape and Berwick 2005). In light of these systemic issues, Table 99–8 highlights ways that physicians can prescribe with greater safety.

Drug of Abuse, Herbal Remedies, and Social Drugs

In addition to taking drugs that are prescribed by caregivers, patients take over-the-counter (OTC) remedies, herbal supplements, street drugs, and drugs of abuse as well as social drugs. These other compounds are subject to the same rules of pharmacology as are prescription medications and can result in pharmacokinetic and/or pharmacodynamic drug interactions with prescribed medications. The results can have great significance. It is important to be aware as fully as possible about all the products that the patients use and try to minimize drug interactions. Table 99–9 describes common OTC and herbal remedies and their role in drug interactions (Reuben et al. 2006).

Interpretation of Evidence

The movement toward evidence based medicine is grounded in the assumption that the evidence is valid, reliable, and clinically meaningful. In contrast to other areas of medicine, psychiatric evidence is more difficult to interpret, and...
there are numerous components of clinical trial design and psychiatric diagnostics that obfuscate the results (Roose and Schatzberg 2005). First, the gold standard trial design for efficacy includes a placebo comparison group. However, placebo treatment involves a host of psychosocial and supportive measures that are not systematically measured. Placebo is not an inactive agent but rather has demonstrable neurobiological effects. For example, the placebo analgesia effect can be localized to the anterior cingulate cortex and is mediated by μ-opioid receptors, and the placebo antidepressant effect may be related to functional connectivity between the ventral striatum, lateral prefrontal, and subgenual cingulate cortices (Benedetti et al. 2005). A placebo response can decrease the sensitivity and power of a trial to detect meaningful effect of a medication and may involve other mechanisms to confuse the results. There exists a correlation between placebo response rate in clinical trials for major depression and year of publication such that the placebo response is becoming more robust with time, relative to active medication (Walsh et al. 2002). Clinical trials in which an active comparator is used are often powered to be noninferiority trials. This leads to the interpretation that medications are equally effective when they may not be. Second, dosing in clinical trials must be at least adequate and ideally optimal. Adequate doses achieve a clinical response, and optimal doses are the lowest doses needed to achieve this full therapeutic response: Dosing becomes even more critical when medications are of different mechanisms or their mechanism changes with drug concentration. For example, venlafaxine is serotonergic at lower doses with an additional noradrenergic component in the middle dosing range of 150 mg, while mirtazapine has this dual mechanism from the initial dose. Trials involving these medications should take these dose effects into account. A third critical component of trial design is the duration of the trial. Treatment must be given at an adequate dose for an adequate duration but must also minimize patient exposure to ineffective treatments. Although clinical trials in depression have been historically of 12 weeks duration, recent evidence has demonstrated that in late-life depression, 4 weeks of treatment may be enough to identify full responders at 12 weeks (Mulsant et al. 2006). Fourth, a diagnostic system based on symptomatology rather than pathophysiology and outcome measures based on small reductions in scores on rating scales rather than remission of illness throw clinical trial data into question (Levine and Fink 2006). Comorbidity in psychiatric diagnoses further diminishes their discriminative value. Rating scales try to approximate improvement in illness burden and can quantify response or remission of symptoms. However, the psychometric properties rating scales can vary and can over- or underrepresent various symptom clusters and components of illness. For example, in the Hamilton Rating Scale for Depression (HAM-D), neurovegetative symptoms are more represented than they are in the Geriatric Depression Scale (GDS). In the Calgary Depression Scale for Schizophrenia (CDSS), negative symptoms of psychosis are discriminated from psychological symptoms of depression (Addington). Whether improving scores on rating scales actually represents clinical improvement is another area of concern. Sedation from a medication can result in improved sleep and thus improvement in HAM-D scores, irrespective of improvement in mood or overall illness severity. Similarly, sedation can improve positive and negative symptoms of schizophrenia (PANSS) scores, in the face of continued psychosis. The fifth concern regarding interpretation of evidence is that of subject inclusion. In the same manner that variabilities in pharmacokinetic or pharmacodynamic parameters can result in differences in the dose–effect relationship, heterogeneity in the in the study population can result in variability in outcomes of clinical trials. Results from a clinical trial sample, which is highly selected, may not be generalizable to the population in clinical settings, and it may be that open-label trials are a better approximation of typical clinical practice. Completion rates in clinical trials affect dosing and labeling as well as safety and efficacy evaluations of psychotropics; these completion rates differ based on psychiatric diagnosis and treatment with medication versus placebo (Khan et al. 2007) again affecting generalizability of results.

In light of the above concerns over design in efficacy trials, recent large effectiveness trials, including the Sequenced Treatment Enhancement Alternatives to Relieve Depression (STAR*D) (Rush et al. 2004), Systematic Treatment Enhancing Program for Bipolar Disorder (STEP-BD) (Sachs et al. 2003), and Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) (Lieberman et al. 2005), have tried to address these concerns. Elders are frequently excluded from clinical trials, and extrapolating adult data to this population may be inappropriate (Lotrich and Pollock 2005). Future trials will try to systematically address clinical questions in real-world practice using representative populations and common treatment algorithms, giving physicians better information on how to prescribe appropriately.

**Summary**

There is an ongoing question about the validity of current clinical trial design in psychiatry. Concerns include high placebo response, clinical trial completion rates, lack of rigorous methodology and data analysis, generalizability of highly selected clinical trial subjects group to the general population, and treatment effectiveness (Roose and Schatzberg 2005). In addition, there is a critical need to enlarge the evidence base across the lifespan, including comparative trials. With respect to safety, the IOM has issued a report highlighting the importance of a “lifecycle” approach to monitoring drugs (Baciu et al. 2006) such that safety issues are addressed not only in early phases of clinical testing, but also long after medications have been released. Historically, drug approval for brand name medications has been expedited, and follow-up safety studies have not always been done by industry. In response to the IOM report, the FDA has initiated changes in the way it does such monitoring (FDA 2007). Given the extensive variability in the dose–response relationship, and the evolving nature of drug safety and efficacy issues, it is imperative that prescribing physicians are aware of the many factors involved in producing both the therapeutic benefits and the adverse events related to drugs. The role of the prescriber is to incorporate often new and uncertain information with his or her best clinical judgment. This chapter has highlighted the potential contributors to the response to psychotropics and the importance of critically addressing the evidence for benefits and risks in the prescription of medications for psychiatric illness.

The advent of the modern era of psychopharmacology in the last half century represents one of the most significant milestones in the history of psychiatry. This relatively young field has not only provided a myriad of interventions that are increasingly safe and efficacious but has also invigorated research to enrich our understanding of the function of the brain, both in normal and in abnormal states. As more effective medications enable a greater number of severely disturbed patients to move from confined settings to community living, the field of psychopharmacology has, furthermore, contributed toward the development of psychosocial rehabilitation programs and the reshaping of the mental health-care delivery system.

The power of these modern-day drugs is demonstrated by the fact that, within a few years of their discovery, they were introduced into practically all geographic areas in the world and quickly became the mainstay for treatment of the mentally ill in all societies (Lin et al. 1993). Similarly, along with the rapid diversification of populations in the USA and other industrialized countries, it has now become clear that the effectiveness and specificity of different classes of psychotropics seem to transcend cultural and ethnic boundaries (Lin et al. 1993). It appears that, in general, psychiatric medications are widely accepted and are regarded as useful and helpful by patients and their families, irrespective of their cultural backgrounds.

Without disputing the universally important role that psychopharmacotherapy plays across different cultures, accumulated practice experiences in divergent cultural and ethnic settings have also revealed numerous reports of cross-cultural/cross-ethnic variations in psychotropic responses (Lin and Poland 1995). Until most recently, practically all psychiatric medications have been developed and tested in North America and Western Europe, involving predominantly Caucasian population. Consequently, scientifically based information regarding the extent of cultural and ethnic influences has been incomplete and scattered. However, both theoretical considerations and data derived from divergent fields have made it increasingly clear that cultural and ethnic factors, similar to age and gender, deserve much more careful consideration than previously thought necessary.

**Dispelling the “Color-Blind” Approach**

Substantial individual variation in drug responses, at times huge differences in terms of optimal dosing, is the rule rather than the exception. Although the current understanding of such remarkable variability remains incomplete, it is clear that the interplay between genetics and environmental factors plays a pivotal role in pharmacotherapeutic responses, particularly in the context of an individual’s ethnic origin, lifestyle, and other sociodemographic variables. Clinicians and researchers have tended to ignore such variables for several reasons: (1) there has been a profound tendency in our field to equate biology with universality and to regard response variations to biomedical interventions as “noise.” (2) when taken out of the context of the often equally substantial, or greater, individual variability that exists in any population groups, findings of ethnic differences run the risk of being interpreted simplistically and stereotypically. Because of these and other reasons, ethnic variations in pharmacological responses have often been regarded with suspicion and are not taken seriously.

However, as shown in Figure 100–1, virtually all factors affecting pharmacological responses are significantly influenced by culture and ethnicity. Furthermore, patterns of genetic polymorphism, often with substantial ethnic
variation, exist in a large number of genes encoding drug-metabolizing enzymes as well as receptors and transporters believed to be targets of pharmaceutical agents. The expression of these genes is often significantly modified by a large number of environmental factors, including diet and exposure to various substances (e.g., tobacco). Of even greater importance, the success of any therapy, including pharmacotherapy, depends on the participation of the patient and those in his/her social network and, as such, depends significantly on the quality of interaction between the clinician and the patient. The importance of culture in this regard is paramount.

### The Cultural Context of Psychopharmacotherapy

Perhaps one of the biggest problems in contemporary medical healing practice is its tendency to focus, often exclusively, on technological biomedical interventions. This tendency frequently obscures the fact that treatment almost always takes place in the context of interactions among individuals. In these interactions, all participants bring their own knowledge, predispositions, values, priorities, modes of thinking, and belief systems into play. Further, these interactions are traditionally discussed in terms of the dyadic relationship between the clinician and the patient. However, both members of the dyad act in concert. No matter how isolated a patient may be, she or he almost always makes decisions within the context of real or imagined input from other people. Similarly, as members of professional groups, clinicians are profoundly influenced by the opinions of their peers and the prevailing ideologies of the field. Moreover, as medical care in most societies becomes increasingly organized, institutional control and influences over the practice of physicians become progressively more prominent. The pharmaceutical industry represents a powerful source of influence on clinicians’ prescription behaviors as well as researchers’ focus and priorities. Thus, while most pharmacotherapeutic decisions may be technical and straightforward in appearance, on closer look they are always imbedded in the rich sociocultural milieu that both the patient and the clinician bring into the transaction (Lin et al. 1993).

Despite their apparent significance, these contextual issues have rarely received adequate attention from both clinicians and researchers. Often they are regarded as “noise” or even “nuisance.” Consequently, there has been a dearth of information regarding the nature and determinants of related issues, such as adherence and the “expectation effect” (including the placebo effect). Even less is known on how sociocultural factors impact these processes. While much awaits further clarification, the extant literature in aggregate does support the suggestion that social and cultural forces play a major role in determining the expectations and behaviors of both clinicians and patients. These in turn affect the process and outcome of the treatment.

### Clinicians’ Attitudes

A large body of literature indicates that patients’ cultural/ethnic backgrounds significantly determine the way clinicians conceptualize and label their problems, which in turn dictate the choices for therapeutic intervention (Mezzich et al. 1995). Using case vignettes that are identical except for ethnic group identification, a number of studies demonstrated that cases identical in every other aspect were nevertheless given significantly more severe diagnoses if the patients were identified as being of ethnic minority origin. For example, African-American psychiatric patients are more likely to have been given a diagnosis of schizophrenia as compared to their Caucasian counterparts (Lopez 1989). Interestingly, in studies where patients were reassessed with the use of structured interviews, such differences largely disappeared, suggesting that such a differential diagnostic pattern is largely determined by variables related to clinicians’ biases rather than to the patients’ clinical conditions (Adebimpe 1981). It is likely that similar biases led to the pervasive use of higher doses of neuroleptics in treating African-American patients, irrespective of diagnosis. Similarly, studies have shown that African-American patients were more likely than their Caucasian counterparts to be treated with depot neuroleptics, presumably due to a general prejudice of their problem with nonadherence (Price et al. 1985).

The potential consequence of these diagnostic and treatment biases may be far from innocent. Several large-scaled studies have documented that the rate of tardive dyskinesia is significantly higher in African Americans (Sramek et al. 1991). Although other reasons for this heightened risk for tardive dyskinesia among African Americans have not been ruled out, it is very likely that their increased exposure to neuroleptics accounts for at least part of such a risk.

### Adherence

The magnitude of the problem with nonadherence to psychotropic medications has commonly been estimated in the range of 20–90% (Becker 1985). Although factors such as insight and motivation may render treatment adherence particularly challenging for psychiatric patients, the problem is far from unique for the field of mental health. In fact, similar high rates of nonadherence have been reported with the treatment of a large number of chronic medical conditions requiring long-term pharmacotherapy. Most studies exploring correlates of nonadherence have focused on patient and treatment variables and have shown that a large number of factors significantly predict problems with adherence. These include the sociodemographics of the patient, the financial burden of the treatment, and the side-effect profile of the medications. The health belief model has served as the theoretical framework for a large number

---

**Figure 100-1** Factors affecting drug response.
of seminal research endeavors, which in aggregate demonstrate that the beliefs held by patients and those significant in their lives to a large extent determine their participation in and response to treatment decisions. The model has also been proven useful in guiding the development of intervention strategies that effectively enhance treatment adherence (Becker 1985). In comparison, little empirical data are available on the influence of factors related to clinician(s) involved in the treatment transaction, the institution(s) where such transactions take place, as well as the nature and quality of the interactions between the clinician(s) and the patient (and those close to him or her).

Following the logic of the health belief model, one would expect adherence to be an even larger problem in cross-cultural clinical situations. This has been substantiated by a number of clinical observations and reports of the service utilization of particular ethnic minority groups. Compared to Caucasians, ethnic minority patients are often found to enter treatment at a significantly delayed stage, and they also are more likely to drop out of psychiatric treatment prematurely. Programs aiming at bridging cultural gaps have been shown to significantly improve treatment retention and outcome (Acosta et al. 1982).

Findings from two studies underscore the importance of cultural factors in determining medication adherence: Kinzie and colleagues (1987) reported that 61% of their depressed medicated refugee patients showed no tricyclic antidepressants (TCAs) in their blood and that another 24% of them revealed only very low TCA serum levels, even though all of them were treated with adequate TCA dosage. When questioned, these patients admitted to nonadherence for a variety of reasons. Education emphasizing the importance of long-term medication and the maintenance of appropriate blood levels resulted in significant improvement in adherence in some, but not all, refugee groups. Similarly, a study in South Africa (Gillis et al. 1987) followed 406 patients belonging to three ethnic groups (whites, blacks, and Asian Indians) for a 2-year period after discharge from a psychiatric hospital. They found that the nonadherence rate for oral phenothiazines was approximately two-thirds for black patients, one-half for Asian-Indian patients, and one-quarter for white patients. The authors noted that the understanding of the treatment protocols by the relatives of the black and Asian-Indian families was particularly poor, with the possibility of culture and communication being significant factors contributing to the results; but one must also consider the impact of structural barriers such as cost and availability of transportation, as well as discrimination. Perhaps for analogous reasons, blacks in the USA are reportedly less compliant and consequently more likely to be placed on injectable antipsychotics (Price et al. 1985).

Adverse effects of psychotropics are often substantial. Various drug-induced symptoms, including not only the classical extrapyramidal and anticholinergic side effects but also the problems such as paradoxical agitation and weight gain, have been found to significantly contribute toward nonadherence and treatment termination. Some of the most dramatic and disabling untoward effects of these therapeutic agents undoubtedly would be regarded with alarm by patients irrespective of their ethnic/cultural backgrounds. However, depending on their beliefs and expectations, many other drug effects could be interpreted as either negative or positive. For example, in a study of Hong Kong Chinese bipolar patients treated with lithium, Lam and colleagues (1992) found that, unlike Western patients, the Chinese rarely complained of “missing the highs” and “loss of creativity” and actually regarded polydipsia, polyuria, and weight gain as part of the therapeutic effect of the medicine. In contrast, lethargy, drowsiness, and poor memory represented serious concerns for many of these patients and were prominent in their complaints, even though objectively they were not likely to be due to the medications they were taking, since they occurred at similar rates among matched controls. Such findings highlight the importance of culturally based beliefs and expectations in determining how physical and psychological experiences associated with drug treatment and recovery are attributed.

The explanatory model (EM) approach, as originally proposed by Kleinman et al. (1978), may be a particularly effective way for the systematic assessment of such beliefs and expectations. By methodically eliciting the patient’s perspectives on the symptoms that are most salient and worrisome to them (patterns of distress), their attributions (perceived causes), their help-seeking experiences and preference, as well as their perception on stigma, discrepancy between the patients’ and the professionals’ EMs could be systematically identified and bridged (Weiss 1997). Elements of the EM are included in Appendix I of the DSM-IV-TR manual as part of the outline for cultural formulation. It is likely that the routine use of such tools will enable clinicians to more effectively enhance adherence, without which no therapeutic interventions can exert their effects.

**Expectation (“Placebo”) Effects**

Although placebo control is an essential ingredient of modern clinical trials, the nature and determinants of the so-called “placebo” effect remain largely elusive and unexplored. Researchers generally recognize that such effects are typically substantial and, in fact, often account for a larger proportion of the improvement than that attributable to the “specific” effect of the therapeutic agent being tested (Swartzman and Burkell 1998). Despite the potency of the “placebo,” it has rarely been the focus of attention to researchers. Consequently, much ambiguity currently exists in regard to this important phenomenon, and there is no consensus regarding which term to use when referring to such effects. The most commonly used term, “placebo,” carries a negative connotation and is easily misunderstood as implying deception as well as ineffectiveness. The term “nonspecific effect” could be similarly misunderstood, since much of the therapeutic effects elicited by “inert” agents might well be mediated through specific biological mechanisms.

The concept of “expectations effect,” commonly used in the field of psychotherapy research, may represent a broader and, at the same time, less controversial notion for such a phenomenon. This term reflects the importance and power of expectation and beliefs on treatment effects in determining patients’ response to any therapy, whether psychosocial or pharmacological. Expectations regarding the safety and effectiveness of any therapeutic interventions, in turn, are shaped by patients’ sociocultural backgrounds as well as individual “idiiosyncratic” experiences (e.g., past experiences of side effects). Since patients’ beliefs regarding medical treatments are often shaped by their cultural backgrounds,
it stands to reason that patients’ expectation regarding the therapeutic effect of the offered treatment would be largely affected by their cultural construct of the illness.

Despite rapid modernization, traditional medical theories and practices remain deeply rooted and influential in determining individuals’ health beliefs and behaviors in many societies. For example, most traditional medical systems emphasize the importance of maintaining a dynamic balance between “coldness” and “hotness” (Castro et al. 1994) or between “Yin” and “Yang” in the case of the Chinese system (Lin 1981). These principles provide guidance for assessment as well as for formulating treatment approaches. For patients who subscribe to such beliefs, a perceived mismatch between the therapeutic agents and the afflictions may significantly lower the expectation effect. For example, red-colored pills might be regarded as capable of enhancing the “hot” element and less effective in the treatment of conditions perceived as a result of excessive “hotness” (e.g., fever, anxiety state, or mania). Interestingly, Buckalew and Coffield (1982) reported findings from a well-controlled study showing significant ethnic differences in response to placebo pills with different colors. In this study, white capsules were seen as analgesics by Caucasian subjects but as stimulants by their African-American counterparts. In contrast, black capsules were seen as stimulants by African Americans and as analgesics by African Americans.

The Concomitant Use of Alternative/Indigenous Treatment and Healing Methods

As mentioned above, the worldwide ascendency of modern “cosmopolitan” (“Western”) medicine has not replaced the traditional or “indigenous” medical and healing systems (Lin et al. 1990). Instead, “alternative” traditions (e.g., Chinese and Ayurvedic medicines) have evolved and continue to be widely used. Multiple medical and healing traditions and treatment modalities coexist in all societies, and patients often utilize these services simultaneously or sequentially, frequently without informing their physicians. This phenomenon has long been observed in “non-Western” countries as well as ethnic minority populations in the USA, although its significance in Western societies has not been adequately appreciated until recent years. When Eisenberg and colleagues (1998) first reported that middle-class Americans (predominantly Caucasians) utilized more “alternative” than “orthodox” medical services, their findings came as a surprise to most health professionals. In the ensuing years, it appears that, both in North America and Western Europe, the popularity of “alternative” medical and healing methods, including many imported from non-Western traditions, has increased exponentially (Eisenberg et al. 1998). Thus, problems with drug–drug interactions that could potentially arise from such practices are no longer limited to particular ethnic groups and constitute an important consideration for clinicians prescribing medications.

Contrary to general perceptions, alternative treatments are not always mild or “benign” and are capable of inducing severe toxic effects. Indeed, various herbs utilized by traditional practitioners and healers are biologically active (it has been estimated that approximately 40% of our “modern” pharmacotherapeutic agents originated from natural sources). Although much remains unclear, herbal preparations do exert significant impact on various biological systems, including those crucial for the functioning of the central nervous system. For example, many herbal preparations possess potent anticholinergic properties and may cause atropine psychosis, particularly when used concomitantly with psychotropics with similar side-effect profiles. Numerous herbs have distinctive stimulant or sedative properties and may either potentiate or attenuate the intended effects of medications prescribed by mental health clinicians. Since most patients do not regard herbs as medicines and typically fail to inform their physicians of such uses unless specifically inquired, toxicities or treatment failures due to “herb–drug interactions” are likely widespread and unsuspected.

As will be further elaborated later, a limited number of enzymes are involved in the biotransformation of all drugs, including psychotropics. Although the activity of these enzymes is crucial for determining the pharmacokinetics and hence the fate and disposition of modern drugs, their primary substrates are not the medications prescribed by physicians but are xenobiotics (natural substances) existing in the environment. Many herbs are thus natural substrates for these “drug-metabolizing enzymes.” Further, through inhibition and/or induction, xenobiotics, including a large number of herbs, exert powerful influences on the expression of these enzymes, which then determine the rate of metabolism of the prescription medications.

Herbal preparations may modulate the effect of modern therapeutic agents, including psychotropics, not only at the pharmacodynamic level (the effect of the drugs on the organism) but also at the pharmacokinetic level. Pharmacokinetic herb–drug interactions occur when the coadministration of an herbal remedy results in the alteration of the absorption, distribution, metabolism, or excretion of the prescribed drug. For example, tetracycline’s antibiotic efficacy is diminished when taken concurrently with the herb, cassia cinnamon (D’Arcy 1991). In this example, tetracycline is absorbed by the cassia bark in the herbal remedy, thereby decreasing its bioavailability. Additionally, tannins contained in tea have been shown to bind psychotropic medications, preventing their gastrointestinal absorption and subsequent entrance into the blood stream and central nervous system (D’Arcy 1991). Herbal medications can also impact the metabolism of a number of different medications, including psychotropics. For example, a number of case studies have cited a decrease in effectiveness of medications such as oral contraceptives (Fugh-Berman 2000) and warfarin (Yue et al. 2000) when taken in combination with St. John’s Wort. The proposed mechanism for these herb–drug interactions is induction of CYP enzymes and/or the p-glycoprotein drug transport system involved in their metabolism by St. John’s Wort (Fugh-Berman 2000). In contrast to the inductive effects of St. John’s Wort, significant inhibition of CYP3A4 and resultant toxicity of medications that are substrates of this enzyme have been noted with grape fruit juice. The results of these studies suggest that grapefruit juice–drug interactions may be due to compounds such as flavonoids, which are also found in fruits, vegetables, and many commonly used herbs (Oesterheld and Kallepalli 1997).

Biological Diversity and Its Consequence in Psychotropic Responses

The central importance of biodiversity in maintaining and ensuring the survival of any species and promoting its
adaptation to the local environment is a fundamental principle that unfortunately has not been adequately appreciated. Possibly because of this underappreciation of the extent and significance of biological diversity in the past, recent findings of the widespread existence of genetic polymorphisms have appeared surprising to many researchers. Emerging data now convincingly demonstrate that for the majority of the genes, polymorphism is the rule rather than the exception. Furthermore, the frequency and distribution of alleles responsible for such polymorphisms often vary substantially across ethnic groups, effectively requiring that ethnicity always be considered in genetic studies (National Institute of Mental Health 1997). These phenomena have long been known in blood and human lymphocyte antigen typing. In recent years, it has become increasingly clear that equally extensive polymorphisms exist in genes governing key aspects of how drugs are metabolized (see Table 100–1) as well as how they affect the target organs. These processes, commonly called pharmacokinetics and pharmacodynamics, are depicted in Figure 100–2 (Greenblatt 1993).

Together, these genetic factors may explain to a large extent the often extensive interindividual cross-ethnic variations in drug responses (Lin et al. 1993). Some of the relevant findings in these regards will be highlighted in the following section.

Genetic Polymorphism of Genes Encoding “Drug-Metabolizing Enzymes”

As shown in Figure 100–2, of the four factors (absorption, distribution, metabolism, and excretion) that together determine the fate and disposition of most drugs, variability in the process of metabolism is most substantial and usually is the reason for interindvidual and cross-ethnic variation in drug responses (Lin and Poland 1995). Most drugs are metabolized via two phases: Phase I, commonly mediated by one or more of the cytochrome P-450 enzymes (CYPs), leads to the oxidation of the substrate; Phase II involves conjugation and is usually mediated by one of the transferases. There is clear evidence of interindividual and cross-ethnic variations in the activity of enzymes in both phases, the genetic basis of which has been increasingly elucidated in recent years. Since far more information is currently available in regard to the CYPs than the Phase II enzymes, and since the CYPs appear to control the rate-limiting steps in the metabolism of most psychotropics, the following discussion will focus mainly on these enzymes.

Table 100–2 includes a list of major CYPs that are responsible for the Phase I metabolism of commonly used psychotropics as well as selected substances that are psychoactive and are commonly used by psychiatric patients. With very few exceptions (e.g., lithium does not require biotransformation; lorazepam and oxazepam are directly conjugated without first going through oxidation), the pharmacokinetics of practically all psychotropics are dependent on one or more of the CYPs, whose activity significantly influences the tissue concentrations, dose requirement, and side-effect profiles of their substrates.

Functionally significant genetic polymorphisms exist in most of the CYPs (Lin and Poland 1995), leading to extremely large variations in the activity of these enzymes in any given population (Table 100–2). CYP2D6 represents the most dramatic example; with more than 50 mutations that inactivate, impair, or accelerate its function (Ingelman-Sundberg 2005). Significantly, most of these mutant alleles are to a large extent ethnically specific. For example, CYP2D6*4, which leads to the production of defective proteins, is found in approximately 25% of Caucasians but is rarely identified in other ethnic groups. This mutation is mainly responsible for the poor metabolizers (PMs) in Caucasians (5–9%), who are extremely sensitive to drugs metabolized by CYP2D6. Instead of CYP2D6*4, extremely high frequencies of CYP2D6*17 and CYP2D6*10 were present in Asian populations, whereas CYP2D6*10 was associated with decreased risk for alcoholism but rare in other populations. Evidences of researches revealed that it has been clearly demonstrated to be associated with a decreased risk for alcoholism.

</table>

This table just presents several examples of different polymorphism frequencies across ethnic groups and how the variations influence the drug metabolisms.

found among those of African and Asian origins, respectively. Both of these alleles are associated with lower enzyme activities and slower metabolism of CYP2D6 substrates (Figure 100–3) and may in part be responsible for previous findings of slower pharmacokinetic profiles and lower therapeutic dose ranges observed in Asians in regard to both classes of psychotropics, and in African Americans in regard to TCAs (Lin and Poland 1995). Interestingly, our recent study showed that Mexican Americans had very low rates of any of these “impairing” mutations. Correspondingly, they also showed significantly faster overall CYP2D6 activity (Mendoza et al. 2001).

CYP2D6 also is unique in that the gene often is duplicated or multiplied (up to 13 copies). Those possessing these duplicated or multiple genes have proportionally more enzymes and faster enzyme activity and are termed “ultra-rapid” metabolizers (UMs). This is found in 1% of Swedish, 5% of Spaniards (white Americans are in between these two figures), 19% of Arabs, and 29% of Ethiopians. UM patients are likely to fail to respond to usual doses of medications biotransformed by CYP2D6, since they typically will fail to achieve therapeutic levels unless treated with extremely high doses of the same drugs. There have been reports of UM patients being regarded as nonadherent because they did not show any evidence of drug effect while given seemingly adequate doses of medications (Akullu et al. 1996).

CYP2C19 represents another dramatic example for the existence of both cross-ethnic and interindividual variations in drug metabolism. This enzyme is involved in the metabolism of commonly used psychotropics such as diazepam and tertiary TCAs, as well as one of the new antidepressants, citalopram. Using S-mephenytoin as the probe, earlier studies demonstrated that up to 20% of East Asians (Chinese, Japanese, and Koreans) are PM, which is true only in 3–5% of Caucasians (Xie et al. 1999). After the gene for the enzyme had been identified and sequenced, it became clear that such enzyme deficiency is caused by two unique mutations (CYP2C19*2 and CYP2C19*3). While *2 can be found in all ethnic groups, *3 appears to be specific to those with Eastern Asian origins. The presence of *3, together with a higher rate of *2, is responsible for the higher rate of PM among Asians, as well as their often increased sensitivity in the clinical setting to drugs such as diazepam (Goldstein et al. 1997).

Genetic polymorphism also exists in CYP2C9, CYP2E1, CYP3A4, as well as the majority of other drug-metabolizing enzymes (see Tables 100–1 and 100–2). It is interesting to note that, almost without exception, wherever genetic polymorphism is identified, the allele frequency of the mutations typically show substantial ethnic variations.

Factors Affecting the Expression of Drug-Metabolizing Enzymes
In addition to genetic endowment, a large number of non-genetic factors also significantly influence the expression of the genes. These factors are both external and internal. External factors include nutrients, various plant products, pharmaceutical agents, and other chemicals. Internal factors include steroid hormones and other endogenous substances. These substances either inhibit or induce the activity of the enzyme and thus affect the metabolism of drugs that are dependent on a particular enzyme. Such shifts in the enzyme status could at times lead to serious clinical consequence. The following are selected examples that have caught the field’s attention in recent years: (1) A number of the newer antidepressants, including fluoxetine and paroxetine, two of the most widely used selective serotonin reuptake inhibitors (SSRIs), are potent inhibitors of CYP2D6, capable of converting an extensive metabolizer into a PM. Thus, when these drugs are prescribed for a patient who has already been taking a CYP2D6 substrate (e.g., TCAs or neuroleptics), the concentration of the latter could be pushed unexpectedly into the toxic range (Brosen 1995). (2) Smoking has long been known to significantly reduce the serum concentration of psychotropics, and it is likely that many patients suffer from relapse soon after discharge from the hospital because they resume smoking (Guengerich et al. 1994). This effect is now known to be due to the induction of CYP1A2 by constituents of tobacco. (3) Many drugs and natural substances significantly inhibit the activity of CYP3A4, altering its ability to metabolize drugs that are
dependent on this enzyme for their biotransformation. A widely known example is the grape fruit juice (Oesterheld and Kallepalli 1997), which is capable of increasing the blood level of antiviral drugs as well as psychotropics such as nefazodone and alprazolam by several folds, if taken concurrently. In addition, reports of lethality caused by the combination of ketoconazole and terfenadine have led to the withdrawal of the latter from the market (Jurima-Romet et al. 1994). (4) A large body of literature indicates that macronutrients (i.e., high protein versus high carbohydrate diet) also significantly influence the activity of CYPs. High protein diet accelerates the metabolism of drugs such as antipyrine and theophylline, and high carbohydrate diet appears to have the opposite effect (Anderson and Kappas 1991).

These examples demonstrate the importance of environmental factors in substantially modifying the activity of drug-metabolizing enzymes. Patients from different ethnic/cultural backgrounds live divergent lifestyles and are likely to be exposed to unique substances that may have strong...
effects on the expression and activity of drug-metabolizing enzymes. Thus, what we currently know about environmental influences on drug metabolism may represent only the tip of the iceberg. This may be especially true in regard to ethnic minority and other non-Western populations. For example, studies have shown that Asian Indians and Africans were significantly slower in metabolizing substrates of CYP1A2, such as theophylline, antipyrine, and clophendramine. However, after they immigrated to Europe and adapted to the new dietary habits, their metabolic profiles for these drugs became indistinguishable from the “native” Westerners (Allen et al. 1977).

As discussed earlier, herbal medicines are routinely and extensively used by people worldwide. Since patients typically are not aware of the potential of herb–drug interactions, they often combine the use of herbs and “Western medicines.” When severe toxic effects subsequently emerge, they usually blame them on drugs prescribed by clinicians, rather than on herbal preparations obtained over the counter, or from traditional/alternative practitioners. Since thousands of herbs are widely in use, and the indication and popularity of these herbs vary greatly across cultural traditions, the potential for interactions between herbs and modern pharmaceutical agents is endless and largely unexplored.

**Genetic Polymorphism of Genes Encoding Receptors, Transporters, or Other Therapeutic Targets**

Monoamines, including dopamine (DA), serotonin (5-HT), and norepinephrine (NE), have been the focus of intensive research attention in the past several decades. In addition to being implicated in the pathogenesis of psychiatric disorders including schizophrenia and major depression, they have also been regarded as the putative targets of psychotropics. Confirming the importance of the 5-HT system in affective and other psychiatric disorders, a number of SSRIs have been developed and are now widely in use for a wide range of clinical conditions. At the same time, although the far more diffuse receptor-binding profiles of the “atypical neuroleptics” call into question the primacy of the “DA hypothesis” in schizophrenia research, the function of the dopaminergic system remains important in understanding the schizophrenic process and its pharmacological management.

Along with the cloning and sequencing of the genes encoding the receptors and transporters that mediate and regulate the function of these important neurotransmitters, it has become apparent that, contrary to earlier predictions, these genes are almost without exception highly polymorphic, and the pattern of these polymorphisms vary significantly across ethnicity. For example, the frequency of the TaqI A restriction fragment length polymorphism (RFLP) polymorphism of the dopamine D2 receptor (DRD2), one of the most extensively investigated brain receptors, ranges from 5% to 18% in Caucasians to approximately 36% in African Americans and 37% to 42% in Asians (Blum et al. 1995). Earlier studies suggesting the existence of an association between this allele and alcoholism have been criticized because ethnicity as a potential confounding variable was not taken into consideration. Similarly, dramatic ethnic variations exist in the pattern of genetic polymorphism of many other receptor and transporter genes. These include other DRD2 mutations (Taq1 B, 311Ser/Cys, and exon 8 A/G substitution), other DA receptors such as DRD4 and DRD3 (Sander et al. 1995), the dopamine transporter gene (DAT1; locus symbol SLC6A3), other DA receptors such as DRD4 and DRD3 (Sander et al. 1995), the dopamine transporter gene (DAT1; locus symbol SLC6A3) (Vandenbergh et al. 1992), the serotonin transporter gene (5-HTT), and a number of serotonin receptors (5-HT3A-1438 A/G and 5-HT3A-102 T/C) (Greenberg et al. 1998).

These polymorphisms are likely to have functional significance and hence might be associated with the risk for psychopathology as well as the response to treatment regimens. For example, recent studies show that the basal transcriptional activity of the serotonin transporter gene (5-HTT) is significantly higher in those possessing a long variant in the promoter region of this gene, which results in differential 5-HTT expression and 5-HT cellular uptake (Greenberg et al. 1998). The clinical significance of these findings was demonstrated in a number of studies of the effect of SSRIs in treating various types of psychotic depression (Kirchheiner and Suringer 2006). In the majority of these studies, patients who were either homozygote or heterozygote long variant (5-HTTTLPR ll and l/s) responded significantly better than those who were homozygote short variant (s/s). However, the frequency of the l allele varies significantly across ethnicity, and it remains unclear if such association exits in groups possessing predominantly the s allele, such as East Asians (Kim et al. 2006). Similarly, DRD2 TaqI A RFLP, located in the l flanking region of the DRD2 gene, has been shown in brain imaging (Hietala et al. 1994) and postmortem (Noble et al. 1991) studies to affect D2 receptor density in different parts of the brain and thus might affect the receptor’s response to neuroleptics, in addition to its possible association with the risk for alcoholism. It is, however, at present unclear if such associations might be true across ethnic groups, and if ethnic differences in the polymorphisms might result in ethnic variations in the pharmacodynamics of drugs whose effects are mediated by these receptors/transporters.

**Genetic Polymorphism of Other Genes Affecting Pharmacological Responses**

The synthesis and catabolism of the catecholamines are controlled by a number of enzymes including tryptophan...
hydroxylase, tyrosine hydroxylase, catechol-O-methyltransferase (COMT), and the monoamine oxidases (MAO). Tryptophan hydroxylase controls the rate-limiting step for the production of 5-HT from tryptophan, and tyrosine hydroxylase plays a central role in the production of DA and NE. On the catabolic side, MAO mediates the oxidation and deamination of 5-HT into 5-hydroxyindole-3-acetic acid (5-HIAA) and other metabolites, and both MAO and COMT are responsible for the metabolism of the catecholamines (DA and NE). Interestingly, all of these enzymes are highly polymorphic. For example, COMT activity has long been known to have a trimodal distribution (McLeod et al., 1994). Recent studies demonstrate that the reduction of its activity is caused by a single nucleotide mutation whose allele frequency is approximately 26% in African Americans, 18% in Asians, and 50% in Caucasians. Higher COMT allele frequency is approximately 26% in African Americans, activity is caused by a single nucleotide mutation whose allele frequency is approximately 26% in African Americans, 18% in Asians, and 50% in Caucasians. Higher COMT activity is correlated with the ratio between 3-O-methyltyrosine and levodopa, which in turn predicts the occurrence of side effects of levodopa in treating Parkinsonism. Reflecting this, a higher percentage of Asians have been found to be poor responders to levodopa (Rivera-Calimlim and Reilly, 1984). It is at present unclear whether, and to what extent, such interindividual and cross-ethnic variations in the polymorphism of these enzymes might influence the pharmacodynamics of psychotropics used in the clinical settings.

Although much less understood, it is commonly agreed that the signal transduction cascade is also of tremendous importance in mediating the effect of psychotropics. Components of this cascade include G-proteins, ion channels, "secondary messengers," and protein kinases. Interindividual and cross-ethnic variations in the genes coding these proteins are likely to exist and may also be responsible for the individual variability in drug response as observed clinically.

Summary and Future Research Directions
This brief survey serves to highlight the significance as well as the complexity of issues surrounding the influence of cultural and ethnic forces on psychotropic responses. Taken together, the literature reviewed above clearly demonstrates the importance of these factors in psychopharmacotherapy. At the same time, it is equally important that any findings regarding ethnic variations in pharmacological responses not be interpreted stereotypically. In this regard, it is useful to keep in mind that almost all ethnic and cultural contrasts are superimposed on usually very substantial interindividual variations in all human groups. This is true not only in regard to biological traits such as the ones reviewed above, but equally so (or even more so) with regard to "cultural" and psychosocial variables. Stereotypic interpretations of cultural and ethnic differences in either psychological or biological characteristics are not only misleading but also potentially divisive and dangerous.

Further, in interpreting biological diversity, both within and across populations, it is important to keep in mind that biological systems are dynamic rather than static, and the expression of genetic predisposition is constantly modified by environmental exposure. This is most clearly demonstrated in the case of the induction and inhibition of the drug-metabolizing enzymes, which could radically alter an individual's metabolic profile, such that a genetically "extensive metabolizer" might appear to possess nonfunctioning gene(s). Although it is reasonable to believe that social and psychological events would similarly exert powerful influences on the functioning of relevant genes, such influences are likely to be far more subtle and complex and have remained largely unexplored.

In addition to culture and ethnicity, other key sociodemographic variables, such as age and gender, have also been known to significantly influence the pharmacokinetics and pharmacodynamics of psychotropics and other pharmaceutical agents. For example, the activity of most P-450 enzymes shows significant decline in older individuals (Kinirons and Crome, 1997), who are also likely to suffer from progressive loss of neuron cells as well as receptors targeted by psychotropics. Both of these changes render the elderly more sensitive to the effects of medications in general. Similarly, steroid hormones including sex hormones have been demonstrated to be substrates of some of the P-450 enzymes and have the capacity to alter the activity of these enzymes. They have also been known to exert powerful influences on some of the brain receptors that might directly or indirectly affect the pharmacodynamics of psychotropics. It is at present unclear to what extent such age and gender effects interact with the effect of ethnicity, and whether such interactions are "synergistic" or "additive." Studies examining such interactions might be of utmost clinical importance, since they might help identify groups with heightened possibility of "unusual" dose response and side-effect profiles.

Progress in the research on P-450 enzymes and other drug-metabolizing enzymes in the past three decades has led to the development of a number of laboratory procedures that could be used for determining the activity of these enzymes as well as polymorphisms of the genes encoding these enzymes. These procedures have been found to be predictive of the pharmacokinetics and side-effect profiles of a number of psychotropics. In addition, emergent data suggest that some of the polymorphisms of genes encoding neurotransmitter transporters and/or receptors might also predict treatment outcome. Thus, it appears that technology may be in place for researchers to systematically test the utility of these procedures in the clinical settings. It is likely that progress in this direction will eventually lead to the development of a panel of genotyping and/or phenotyping procedures that could be used by clinicians to guide their decisions in terms of the choice of antidepressants, the starting dosage, strategies for titration, as well as the prediction of likely side effects. Such a panel will not only enhance the treatment response rate, but also reduce the duration for dose titration, minimize the development of untoward effects, and thus ensure better treatment compliance. Thus, it should also result in treatment strategies that are not only more effective but also more cost effective than "traditional" titration methods. With the development of high throughput of gene array technologies, such as the matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (TOLFI MS) (Ross et al., 1998), thousands of samples could be processed on a daily basis, so that the turnaround time for test results could be short enough to be useful for clinicians ordering such tests. Together, these exciting new developments should help make psychopharmacotherapy increasingly more rational, evidence based, and effective.
The progress in pharmacogenomics might also stimulate research on "nonbiological" issues such as cultural influences on adherence to therapy and other factors that determine patients’ perception and help-seeking behavior, which in turn contribute toward their sense of satisfaction and their being able to maximally benefit from psychotropic treatment. With such an integrative approach, we would be best able to define elements for optimal pharmacotherapeutic practices that would take both cultural and biological diversity into consideration and tailor treatment to individual characteristics rather than relying on global guidelines.

This chapter reviews current knowledge about antidepressant medications. Theoretical and clinical data will be considered, particularly those representing recent developments in this field. The use of antidepressants in the treatment of depression remains the best-understood use of these medications, and this is the focus of the chapter.

Theoretical Basis for Treatment

The discovery of antidepressants did more than provide a revolutionary therapy for depression; it has slowly helped to change the concept of mood disorders and, by analogy, the mind itself. Although other somatic antidepressant treatments preceded antidepressants (most notably electroconvulsive therapy), the widespread use of antidepressants for all types of depression (i.e., those thought to be “exogenous” as well as “endogenous”) forced psychiatrists to re-appraise their ability to influence areas of existence previously thought unreachable through physical manipulation.

The Development of Antidepressants

There are a number of good reviews of the history of antidepressants. A paper by Pletscher (1991) provided many of the data for this discussion.

The first antidepressant was the monoamine oxidase inhibitor (MAOI), iproniazid. It was soon followed by the tricyclic antidepressant (TCA), imipramine. Although both were developed in the early 1950s, they represented different paths of discovery: iproniazid was the result of clinical and laboratory collaboration, whereas imipramine’s introduction was largely based on clinical observation. Imipramine’s mechanism of action was clarified only later.

Iproniazid was synthesized from isoniazid in an attempt to improve the chemotherapy of tuberculosis. Three unexpected actions of the drug—monoamine oxidase inhibition, reversal of reserpine-induced sedation, and psychostimulation—resulted in its introduction as the first modern antidepressant. Serious side effects, particularly hypertensive crises and hepatic necrosis, prevented general acceptance of the drug.

Imipramine was synthesized from chlorpromazine. Unlike its parent, imipramine proved ineffective as an antipsychotic, and research on it was almost abandoned. Clinical investigators, however, observed that imipramine had a beneficial effect on depression. Equally important, it did not show the serious side effects associated with iproniazid. Imipramine eventually became widely accepted as a safe and effective antidepressant.

Mechanisms of Actions

Investigations into the biochemistry of depression have taken their lead from antidepressants. All known antidepressants affect monoamine neurotransmission, and this is believed to be their mechanism of action. Research into these monoamines evolved into the monoamine hypothesis of depression.

The Monoamine Hypothesis of Depression

The monoamine theory of depression suggests, in its simplest form, that depression relates to abnormal levels of monoamines: neurotransmitters thought important in the regulation of mood. Antidepressants themselves provide the strongest evidence supporting the role of monoamines in mood, as all known antidepressants affect the levels of monoamines in the brain. Other evidence for the monoamine hypothesis included the observation that reserpine (which depletes norepinephrine and serotonin) frequently causes depression.

Originally, norepinephrine was the monoamine thought to be most involved with mood, as most of the early antidepressants primarily affected this transmitter. Newer drugs had more of an effect on serotonin; as a result, this too became a focus of theories on depression. Serotonin may have a direct effect on mood, and may interact in a regulatory way on norepinephrine. It has been shown repeatedly that tryptophan depletion (the precursor for serotonin) can render antidepressants ineffective. This is true regardless of whether the antidepressant is thought primarily to affect noradrenergic systems, thus supporting the regulatory function of serotonin (Reilly et al. 1997). TCAs also block reuptake of dopamine, and several antidepressants seem to act primarily on the dopamine system, including bupropion and nomifensine. Dopamine may interact with norepinephrine, perhaps through augmentation of alpha-1-receptors.

Several observations argue against the adequacy of the monoamine theory of depression. For example, investigators have been unable to demonstrate consistently
Inherent limitations in antidepressant response. Alteration in the same antidepressant effect. Different chemicals, with different potential actions, can have extracellular effects are transduced to a limited number of intracellular mechanisms as adenyl cyclase. Though the details are complicated, the relevance to antidepressants is simple: a variety of transmitter and receptor effects. That is, receptors are linked to G-protein. The activation of the receptor by a neurotransmitter brings about a functional change in the G-protein. G-protein is then able to bind to GTP, which then affects intracellular concentrations of such second messengers as adenyl cyclase.

Receptors

Looking for a more complex correlate of antidepressant action, investigators focused on transmitter–receptor interactions. Vetulani and Sulser (1975) described beta-adrenoceptor down regulation in response to antidepressant administration. This receptor effect was demonstrated in animal experiments, and observed with all antidepressants. Down regulation of the beta-receptor not only involves the noradrenergic system, but also requires an intact serotonin system as well. Down regulation also shows a time lag, making it a better model of antidepressant action. When investigators administer antidepressants to animals for a significant time, they consistently find both reductions in the number of beta-adrenoceptor recognition sites and a down regulation of beta-adrenoceptor functioning. Increased monoamine availability affects not only beta-receptor down regulation, but also up regulation of the alpha-receptor, an autoreceptor that regulates neurotransmission (Ackenheil 1990). Of the serotonin receptors, 5-hydroxytryptamine type 1A (5-HT1A) appears most related to the therapeutic effects of antidepressants. This receptor influences norepinephrine, dopamine, acetycholine, neuropeptides, other serotonin receptors, and probably beta-receptor down regulation.

The most compelling argument for depression-associated receptor changes would be a direct demonstration of such an association in humans. The availability of selective ligands for specific receptors has begun to lend support to such hypothetical associations. A number of serotonin receptor subtypes have been shown to have a reduction in sensitivity in response to selective serotonin reuptake inhibitor (SSRI) administration, including 5-HT1A (Cowen et al. 1994) and 5-HT1D (Whale et al. 2001). In both cases, these receptor changes were seen most markedly in patients with melancholic depression.

Intracellular Systems

Second-messenger systems offer a final common pathway for the variety of transmitter and receptor effects. That is, despite the myriad of ways in which receptor and transmitters can be affected, the result is the overall effect on intracellular mechanisms. Most of the monoamine receptors are linked to G-protein. The activation of the receptor by a neurotransmitter brings about a functional change in the G-protein. G-protein is then able to bind to GTP, which then affects intracellular concentrations of such second messengers as adenyl cyclase. Though the details are complicated, the relevance to antidepressants is simple: a variety of extracellular effects are transduced to a limited number of intracellular responses. This may explain how many different chemicals, with different potential actions, can have the same antidepressant effect.

The role of G-protein may also explain some of the inherent limitations in antidepressant response. Alteration in G-protein synthesis and activity takes several weeks, which is consistent with the latency in effect of antidepressants. Though G-protein may be crucial in understanding the overall antidepressant effect of drugs, it probably is not directly related to an antidepressant’s mechanism of action. The action of most antidepressants seems to be extracellular, and there is no evidence to suggest that any antidepressant has a direct effect on the G-protein. Other medications, such as the lithium ion, may directly influence GTP binding, and this may explain lithium’s efficacy as an adjunctive medication.

The relationship between neurotransmitter activity and the mechanism of antidepressant action is depicted in Figure 101–1.

Beyond the Monoamines

Newer theories attempt to include new information from neurophysiologic and genetic studies. For example, brain-imaging studies suggest that there is subtle atrophy in hippocampal and other limbic structures in depressed individuals. These findings may relate to hypothetical abnormalities in the genetic transcription of brain-derived neurotrophic factor (BDNF). BDNF is involved in neurogenesis and stability; however, when exposed to environmental stress, the gene for BDNF is inhibited, which leads to atrophy of vulnerable neurons (Duman and Monteggia 2006). A full discussion of this exciting research is not possible here; however, it is of great interest as it points to treatments that are not solely based on monoamine theories. Some implications of this and related research are discussed at the end of this chapter.

Antidepressants: Taxonomy and Relation to Mechanism of Action

Antidepressants are grouped in several ways. One is historical, in which antidepressants are roughly divided by the period in which they were introduced (e.g., such terms as “first-generation” antidepressants). Another is by chemical structure (e.g., “tricyclic” antidepressants). Alternatively, they are classified by their presumed mechanism of action (“selective serotonin reuptake inhibitors”). In practice, a combination of these is used; thus, some TCAs, which primarily act through serotonin reuptake inhibition (e.g., clomipramine), are usually included with other TCAs rather than as an SSRI, even though they could rightly claim membership in either category.

First-Generation Antidepressants

These were the first antidepressants developed. Most were discovered through serendipity. They include the monoamine antidepressants and the TCAs.

Monoamine Antidepressants (MAOIs)

Historically, these are the first antidepressants discovered. They are all characterized by their unique mechanism: they inhibit the action of monoamine oxidase (MAO), the primary catabolic enzyme for the monoamines. The result is an overall increase in available monoamines. However, owing largely to their side effects, and dietary restrictions, they have rarely enjoyed popular use. Recently, however, a transdermal formulation of selegiline has been introduced, reducing the concentration of MAOI in the gastrointestinal tract, and diminishing the likelihood of diet-related side effects.

(continues)
The monoamines norepinephrine, serotonin, and dopamine are synthesized within the neuron (1) from dietary amino acids, and then stored within vesicles (2). This vesicle can then bind with the axonal membrane, releasing its contents into the synapse (3). Upon binding to a receptor complex (4), a resultant cascade of reactions is possible. In general, the binding process causes a destabilization of the subunits comprising the receptor-G-protein complex (5). G-protein, now activated, can then regulate a number of second-messenger systems, such as adenylate cyclase and phospholipase C. The potential results can involve alterations at various levels of neuronal function; from physical structure and membrane permeability to direct regulation of genetic transcription. In this way, it is possible for the many brief and simultaneous inputs to be transduced into coherent and lasting influences on neuronal function. Neurotransmitters can even regulate their own production through binding to presynaptic autoreceptors.

Once the reaction is complete, the receptor-G-protein complex restabilizes, and the monoamine is released from the receptor site. The neurotransmitter can then be metabolized in the extracellular space or, more commonly, taken back in the axon through a transporter site (6). Monoamines undergoing such reuptake can be again stored within vesicles, or be deaminated by intracellular monoamine oxidase (residing on the wall of mitochondria) (7).

Tricyclic Antidepressants (TCAs)

These medications all have a structural similarity in common. They are subdivided by the number of amine groups they possess, hence their designation as “tertiary” or “secondary” TCAs. Several are related by metabolism; thus the tertiary amines—amitriptyline and imipramine—are metabolized to the secondary amines—nortriptyline and desipramine—respectively. They all act through reuptake inhibition, and are generally selective for the norepinephrine transporter; several, however, have equal or greater affinity for the serotonin transporter. Normally, excess monoamine is taken up through monoamine transporters into the neuron, where it can be stored, or, more often, catabolized by intracellular MAO. Reuptake inhibitors prevent this through inhibition of the transporter; the excess neurotransmitter remains in the synaptic space where it can bind with receptors. That this
is the mechanism of action of these and many other antidepressants, is reinforced by the fact that correlations have been demonstrated between transporter inhibition and clinical improvement in depressive symptoms (Hrdina et al. 1997). The TCAs were the drugs of choice for depression throughout the 1980s. Though very effective, their somewhat nonselective actions, acting on cholinergic, presynaptic adrenergic receptors, for example, resulted in a number of side effects.

Second-Generation Antidepressants
These medications were developed using knowledge gained from the first-generation antidepressants. An effort was made to produce medications with more selective actions. The primary benefit of such selectivity was a decrease in unintended side effects.

Selective Serotonin Receptor Inhibitors (SSRIs)
The SSRIs were first introduced in the late 1980s. Within a few years, they eclipsed the TCAs as the drugs of choice for depression. As the name suggests, they all act through inhibition of the serotonin transporter. Though very similar, they have some subtle differences, mainly in terms of their half-life, their potency for reuptake inhibition, and their affinity for some other receptors.

Fluoxetine was the first SSRI available in the US. It was introduced in 1986 and has been used in over $4$ million patients worldwide. Sertraline has been available in the US since 1992 and by the late 1990s it became one of the most popular medications ever prescribed: by the time the US patent expired in 2006, it was estimated to have grossed over $3$ billion dollars in sales. Paroxetine was first introduced in 1993 and it gradually overtook sertraline in sales; by 2005, it was the most prescribed drug of any type. Citalopram and fluvoxamine, both introduced later, have similar data attesting to their efficacy in depression. Escitalopram is the $S$-enantiomer of the SSRI citalopram. Pharmacologic studies indicate that this form is predominantly responsible for the 5-HT reuptake by racemic citalopram. This drug became the second most prescribed medication in the US in 2005.

Selective Norepinephrine Reuptake Inhibitors (NRIs)
Like the SSRIs, medications in this class share a similar mechanism with the SSRIs, but act on the norepinephrine transporter and have little affinity for the serotonin transporter. Atomoxetine is an example of an NRI; currently it is approved for use in attention-deficit/hyperactivity disorder; however, there is evidence to suggest that it is useful for depression as well (Kratochvil et al. 2005). Reboxetine (not currently available in the US) is another example of such a medication.

Tetracyclic Antidepressants
This class includes trazodone, which was structurally related to the TCAs but has a primary serotonergic mechanism.

Norepinephrine–Dopamine Reuptake Inhibitors (NRDIs)
Bupropion, an aminoketone, is an unusual antidepressant in that it is structurally more similar to several stimulants (cathinone, diethylpropion and the phenethylamines) than to previous antidepressants. It appears to have a clinically significant effect on both dopamine and norepinephrine reuptake.

Currently, it is approved both as an antidepressant and as a smoking cessation aid. In addition, radafaxine, a potent metabolite of bupropion, is currently in clinical trials.

Dopamine Reuptake Inhibitors (DRIs)
Several antidepressants have been introduced, both in the US and internationally, which appear to act primarily through inhibition of dopamine reuptake. Most are no longer available, because of either side effects or abuse potential. Nomifensine, initially studied in the 1970s, is no longer commercially available after international reports of severe hemolytic anemias were reported. Aminiptine, a potent dopamine reuptake inhibitor (which, to a lesser degree, also inhibited norepinephrine reuptake), is now banned in most countries because of its abuse potential.

Third-Generation Antidepressants
The next generation of antidepressants involved various attempts to expand the potential of second-generation compounds. One important feature of this group is that many of them have multiple actions. In some cases, this involves actions on multiple neurotransmitters. In other cases, it involves multiple mechanisms of action.

Even though this may seem a return to the broader acting first-generation compounds, the attempt with these drugs is to maximize the presumed “clinically relevant” effects of the drugs, while minimizing the less important (and potentially adverse) actions.

Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)
These antidepressants share a common mechanism with the SSRIs, but differ in that they have equal affinity for the norepinephrine and serotonin transporter. Medications in this class include venlafaxine and duloxetine. Other medications (available in other countries), such as milnacipran, have similar mechanisms of action. Although, like several of the TCAs, venlafaxine and duloxetine have multiple receptor effects, and are relatively free of the anticholinergic and antihistaminic side effects that are common with the TCAs.

Mixed Serotonin Antagonist/Reuptake Inhibitors
These agents have multiple mechanisms of action, all of which appear to be of clinical importance. Nefazodone is an example of such an agent, with both serotonin (as well as norepinephrine) transporter inhibition as well as antagonism of 5-HT2A and alpha-1-receptors. Trazodone may be similar; however, its effects are somewhat less specific, and as a result, it resembles the TCAs in most respects.

Noradrenergic and Specific Serotonergic Antidepressants (NaSSAs)
Currently, the only agent in this class is mirtazapine. This agent is unique in that it appears to work primarily through receptor blockade, specifically through blockade of the alpha-2-autoreceptors on presynaptic noradrenergic neurons, which enhances noradrenergic output. They may exert a similar effect toward autoreceptors on serotonin neurons. Antagonism of 5-HT2 and 5-HT3 receptors may also concentrate the effect of serotonin on 5-HT1A receptors.

The antidepressants available in the US (as of the second quarter of 2007), their class, and relative costs are listed in Table 101–1.

**The Basis for Determining Efficacy**

**Clinical Trials**

As with any drug, the gold standard for proving efficacy is a double-blind placebo-controlled trial. There have been many such studies for antidepressants. As a whole, these studies lend strong support for the efficacy of antidepressants.

There have been some limitations in these data. Some have questioned the effectiveness of the blinding techniques, and it has been demonstrated that subjects in some...
supposedly blinded studies can accurately guess whether they are on a drug or a placebo. Such potential bias could inflate the perceived efficacy of these drugs (Moncrieff et al. 1998). A somewhat opposing dilemma is the high placebo response in many intervention studies on depression, requiring large samples before a significant effect can be found. These biases, though important, have occasionally been exploited with the purpose of discrediting data proving the efficacy of antidepressants. However, there are very many carefully performed studies investigating antidepressants, and the sheer enormity of these add considerable weight to the contention that these drugs are very effective in the treatment of major depressive disorders.

**First-Generation Antidepressants**
Since the first reports of the efficacy of amitriptyline (Kuhn 1958) and imipramine (Kline 1958), numerous controlled trials have demonstrated the efficacy of first-generation antidepressants. A potential antidepressant is compared to either a placebo or a gold standard antidepressant, usually imipramine. All TCAs have been shown to be either superior to placebo or equal to imipramine in the treatment of depression. Overall, the first-generation agents have been found to be comparable with each other, although there has been some suggestion, admittedly controversial, that the MAOIs are not as effective as the TCAs in severe “typical” depression (Thase et al. 1995), but that they may have a preferential action in patients with “atypical” depression (Quitkin et al. 1990).

**Second-Generation Antidepressants**
All of the second-generation antidepressants have shown efficacy in randomized controlled trials when compared to placebo or to older antidepressants (Williams et al. 2000). The majority of drug trials involving second-generation antidepressants have been in outpatient populations. However, there are increasing studies that examine these drugs in more complicated patients, including the severely depressed (Hirschfeld 1999). Similarly, the majority of the studies investigate the treatment of acute depression.

**Third-Generation Antidepressants**
All of the third-generation antidepressants have shown efficacy in randomized controlled studies when compared to placebo or other antidepressants (Williams et al. 2000). There is modest evidence to suggest that some of these agents may have improved efficacy or time to effect; this evidence is discussed in the next section.

**Comparative Trials**
Is one antidepressant any more efficacious than another? In studies employing various comparisons, antidepressants of different classes are generally found to be equal in efficacy. There are some caveats to this statement. As already noted, placebo-response rates in many studies of depression are quite high, and it is difficult to show a statistically significant effect. Large sample sizes are needed: assuming that any difference between two antidepressants is likely to be small; a study would require thousands of subjects before it could detect this difference in efficacy. Some of these limitations can be addressed by meta-analyses, which pool the results from different studies to increase the sample size. However, the use of meta-analysis has inherent limitations and a potential for bias, and cannot replace well-done controlled studies.

**SSRIs Compared with Other SSRIs**
In a 2005 review, Hansen et al. (2005) identified 22 studies comparing one SSRI with another SSRI. They rated 21 of the studies as “fair” and 1 as “good.” Three of the studies were classified as “effectiveness studies” (in that they replicated “real-world” treatment conditions); the remainder was classified as efficacy trials. The majority of studies found no difference in efficacy or effectiveness between individual SSRIs. Occasionally, studies did find differences on a single outcome measure. For example, one comparative study found greater efficacy for escitalopram when compared with citalopram (Lepola et al. 2003). Another study found that paroxetine had greater efficacy when compared with fluoxetine (Shone and Ludwig 1993). In both cases, other similarly designed trials did not find differences. On other clinically important measures, such as speed of response, the different agents were generally found to be equivalent.

Again, individual studies occasionally found small differences in the speed of response, but similar studies did not confirm this difference. Hansen and colleagues concluded that the reported differences were the result of chance in relatively small studies. They also noted that the majority of published studies were funded by pharmaceutical companies and that when differences were found they inevitably favored the company’s product.

**SSRIs Compared with Other Antidepressants**
Hansen et al. (2005) also investigated studies comparing SSRIs with other second- and third-generation antidepressants. They found 24 efficacy trials: 21 were rated as “fair” and 3 were “good.” Most trials found similar efficacy. However, a number of studies found better rates of response with venlafaxine when compared with other agents. Only a few reached statistical significance: 1 compared venlafaxine with sertraline (Mehtonen et al. 2000), and 2 compared it with fluoxetine (Dierick et al. 1996, DeNayer et al. 2002). However, the majority of studies comparing venlafaxine with another agent did not find a statistical difference and efficacy. Hansen and colleagues could not find a reason to explain these conflicting data, and differences in study design did not seem to explain the disparities. Study size may again play a role; it is notable that in one pooled analysis of eight double-blind studies comparing venlafaxine with SSRIs (all of which individually showed no difference between the drugs), Thase and colleagues (2001) did report a significant difference in remission rates between venlafaxine, which began at 2 weeks. One must conclude from these data that if a difference does exist, it must be small.

Some differences have been found on other measures. Mirtazapine has consistently been shown to have a faster onset of action than comparable SSRIs, although the SSRIs catch up by the end of each study. This was shown in comparison with fluoxetine (Hong et al. 2003), sertraline (Behnke et al. 2003), and paroxetine (Benkert et al. 2000, Schatzberg et al. 2002). Venlafaxine has occasionally been shown to have a faster response time; however, the data are mixed and conflicting.
Summary
Numerous controlled studies support the efficacy of the antidepressants for the treatment of depression. The bulk of data suggests that all antidepressants have equal efficacy. As new drugs are introduced to the market, one sees a variation on the two primary themes: selectivity versus multiplicity. Agents that are more selective potentially offer cleaner profiles with fewer side effects. However, there are some data to suggest that multiacting agents can offer advantages, including improved efficacy or faster action. These pharmacological strategies seem more likely to be successful in improving side effects rather than dramatically improving efficacy. Modest improvements in efficacy may be possible; ones that are more dramatic will likely have to wait for truly unique agents to be developed. Finally, effectiveness studies in real world settings suggest that remission rates may be more modest than that reported in efficacy trials.

The Development of New Antidepressants

Animal Trials
The development of a new drug is generally divided into three phases: phase I is an initial screening for a desired activity; phase II is a more elaborate determination of desired activity and pharmacokinetics; and phase III is a definitive judgment of the drug's pharmacology. Of particular interest is the phase I, or initial screening of a drug. In the past, such a screening was largely a matter of serendipity. Methods that are more analytic have largely supplanted this. Such methods can take two approaches: a behavioral approach, or a mechanistic approach. In a behavioral approach, investigators attempt to develop an animal model of a particular pathological condition. In a mechanistic approach, the investigator targets particular actions of a potential drug—actions that are presumed to be the basis of a therapeutic effect.

Behavioral Models
Traditionally, investigators rely on animal models that attempt to reproduce psychiatric pathology. Three examples of such tests are the separation syndrome in rhesus monkeys (McKinney 1988), learned helplessness models (Seligman and Maier 1967), and the behavioral despair or “forced swimming” test (Porsolt et al. 1979). Most behavioral tests are complicated and expensive to perform. The behavioral despair test is probably the most practical of these tests. In this test, an investigator places a mouse or rat in a confined space filled with water. Usually, the immured animal will first attempt to escape, and then become immobile: “behavioral despair” refers to the assumption that the animal has given up hope of escaping. On subsequent immersions, the animal becomes immobile more quickly. Most antidepressants, regardless of class, delay this effect, and the ability of a new agent to delay immobility in animals is a good predictor of antidepressant action in humans. There is even a correlation between the potency of an agent in this test and its clinical potency as an antidepressant: this feature is not demonstrable in any other animal model of depression (Willner 1990). The mechanism of this response has been shown to be mediated by both pre- and postsynaptic serotonergic 5-HT1 receptors (Redrobe et al. 1996); however, the behavioral despair is not necessarily limited to these receptors alone.

Mechanistic Models
The most common mechanistic tests evaluate antagonism of reserpine—a feature of all TCAs and many newer agents. Several experiments evaluate different examples of reserpine antagonism. The ability to block reserpine-induced hypothermia depends on an agent’s proficiency at increasing postsynaptic norepinephrine or potentiating beta-adrenergic receptors. Antagonism of reserpine-induced ptosis is dependent on alpha-noradrenergic or serotonergic activity, and antagonism of reserpine-induced akinesia appears to be dopamine dependent. In combination, these three tests can differentiate between several monoamine-dependent effects. Other methods include antagonism of oxotremorine (related to anticholinergic activity), the high-dose apomorphine test (specific for norepinephrine reuptake), and the yohimbine test. The ability to potentiate yohimbine lethality, an alpha-2-agonist, appears to be highly specific for antidepressants.

Thus, a variety of psychopharmacological tools may be of use in screening potential antidepressants. They are generally simple to perform and relatively inexpensive, particularly when compared with clinical trials. They may also be more reliable than standard neurochemical screening in predicting the antidepressant action of an agent (Bourin 1990).

Limitations of Behavioral and Mechanistic Models
An ideal model of depression should be able to meet the same criteria as any model of human disease. It should reproduce the symptoms and the etiology of the disease, show common biological mechanisms, and show reversal of symptoms by proven therapeutic agents (Delina-Stula 1989). Neither the behavioral model nor the mechanistic model of depression meets all these criteria. The behavioral model suffers from inherent limitations in attempting to simulate a complex human behavior in an animal. Usually, one compromises by simulating certain aspects of depressive behavior in an animal. Such a “target symptom” may not be a true extrapolation of human depression. Though recent attempts to breed for “depressed” mice (Vaugeois and Costentin 1998) (using a predilection toward helplessness behaviors as a target symptom) might improve the situation, the behavioral models continue to suffer from significant limitations. Behavioral models can also be cumbersome and expensive.

Mechanistic models are simple and inexpensive, but suffer from limited specificity (e.g., aspirin, with no antidepressant action, can antagonize reserpine-induced hypothermia) and a reliance on available theories about the critical ingredient of antidepressants. For this reason, the mechanistic model is less likely than the behavioral model to reveal truly novel antidepressants. Used together, the two models can complement each other.

A potentially greater inherent limitation is that these models, to date, have only been successful in identifying drugs that work through actions on monoamine neurotransmitters. This may simply reflect the fact that these types of drugs are the most frequently tested; however, the fear is that this reflects a more fundamental problem that the models are only testing for disturbances in monoamine activity. If this is true, then these models will be limited in their ability to identify novel treatments for depression,
and new models may be required. Models based on neurophysiologic and genetic data are being developed; the implications of these newer paradigms are discussed at the end of this chapter.

The Formulation of Treatment

Indications

Acute Major Depression
